

Figure 3 Depicted are the key anatomic relationships in levels I and II that must be kept in mind in performing a neck dissection. View is of the right neck.

ascends to the skull base between the external carotid artery and the internal jugular vein. Often the hypoglossal nerve is surrounded by a plexus of small veins, branching off the common facial vein. Bleeding in this region places the hypoglossal nerve at risk. The jugular vein, located just posterior to the external carotid artery and the hypoglossal nerve, may be isolated and doubly suture-ligated at this point. Frequently, the spinal accessory nerve is identified just lateral and posterior to the internal jugular vein, proceeding posteriorly into the sternocleidomastoid muscle.

In a radical neck dissection, the sternocleidomastoid muscle and the spinal accessory nerve are transected at this point and elevated off the splenius capitis and the levator scapulae to the trapezius posteriorly. The anterior edge of the trapezius is skeletonized from the occiput to the clavicle. In a radical neck dissection, the accessory nerve is again transected where it penetrates the trapezius.

*Step 3: Control of Internal Jugular Vein Inferiorly;
Ligation of Lymphatic Pedicle*

The sternal and clavicular heads of the sternocleidomastoid muscle are transected and elevated to expose the anterior belly of the omohyoid muscle. The soft tissue overlying the posterior belly of the omohyoid muscle is clamped and ligated as necessary. The omohyoid muscle is then transected, and the jugular vein, the carotid artery, and the vagus nerve are exposed. The jugular vein is isolated and doubly suture-ligated. Care is taken not to transect the adjacent vagus nerve and carotid artery. The lymphatic tissues in the base of the neck adjacent to the internal jugular vein are clamped and suture-ligated 1 cm superior to the clavicle. If a chyle leak is encountered, a figure-eight stitch is placed along the lymphatic pedicle until there is no evidence of clear or turbid fluid on the Valsalva maneuver. Care is taken to avoid inadvertent injury to the vagus nerve or the phrenic nerve, which course through this region.

*Step 4: Mobilization of Supraclavicular
Fat Pad ("Bloody Gulch")*

The fascia overlying the supraclavicular fat pad is incised, and the supraclavicular fat pad is bluntly retracted superiorly so as to free the tissues from the supraclavicular fossa. If transverse cervical vessels are encountered, they are clamped and ligated as necessary. Fascia is left on the deep muscles of the neck, which also envelop the brachial plexus and the phrenic nerve.

Step 5: Dissection and Removal of Specimen

Attention is then turned to the posterior aspect of the neck. Fat and lymphatic tissues are retracted anteriorly with Allis clamps, and the specimen is dissected off the deep muscles of the neck with a blade. Again, a layer of fascia is left on the deep cervical musculature: stripping fascia off the deep cervical musculature results in denervation of these muscles, which adds to the morbidity associated with accessory nerve sacrifice. Once the specimen is mobilized beyond the phrenic nerve, the cervical nerves (C1–C4) may be divided. The specimen is peeled off the carotid artery and removed.

Step 6: Closure

The neck incision is closed in layers over suction drains.

MODIFIED RADICAL NECK DISSECTION

The incision is made and flaps are elevated as in a radical neck dissection. Care must be exercised in elevating the posterior skin flap. Typically, the platysma is deficient in this area, and often no natural plane exists. Dissection deep in the posterior triangle may result in inadvertent injury to the spinal accessory nerve, which travels inferiorly and posteriorly across the posterior triangle in a relatively superficial plane to innervate the trapezius.

A type I modified radical neck dissection begins with dissections of levels I and II, as described for a radical neck dissection (see above). The spinal accessory nerve is identified just superficial or posterior to the internal jugular vein and preserved; the distal spinal accessory nerve is then identified in the posterior triangle. Typically, the spinal accessory nerve can be identified 1 cm superior to the cervical plexus along the posterior border of the sternocleidomastoid muscle. Provided that the patient is not fully paralyzed, the surgeon can distinguish this nerve from adjacent sensory branches by using a nerve stimulator.

Once the spinal accessory nerve is identified, it is dissected and mobilized distally. Proximally, the nerve is dissected through the sternocleidomastoid muscle, which is transected over the nerve. The branch to the sternocleidomastoid muscle is divided with Metz scissors, and the nerve is fully mobilized from the trapezius posteroinferiorly to the posterior belly of the digastric muscle anterosuperiorly and then gently retracted out of the way.

The rest of the neck dissection proceeds as described for a radical neck dissection. If the tumor does not involve the internal jugular vein, it may also be preserved; this constitutes a type II modified radical neck dissection. If the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle are all preserved, the procedure is a type III modified radical neck dissection. In a type III dissection, the sternocleidomastoid muscle is fully mobilized and retracted with two broad Penrose drains, and the contents of the neck are exposed. The spinal accessory nerve is preserved throughout its entire course, including the branch to the sternocleidomastoid muscle. The remainder of the neck dissection proceeds as previously described (see above).

SELECTIVE NECK DISSECTION

Levels I to IV

In a selective neck dissection, the posterior triangle is not removed; thus, there is no need to elevate skin flaps posterior to the sternocleidomastoid muscle. Limited elevation of skin flaps is beneficial, particularly for patients who have previously undergone chemoradiation therapy, in whom extensive flap elevation may contribute to significant persistent lymphedema after operation. Subplatysmal skin flaps are raised sufficiently to expose the neck levels to be dissected, with the central compartment left undisturbed. If level I dissection is planned, the fascia overlying the submandibular gland is raised and retracted so as to preserve the marginal nerve. The submental fat pad is grasped and mobilized away from the floor of the submental triangle (composed of the anterior belly of the digastric muscle and the mylohyoid muscle). Inferiorly, the lymphatic tissues are mobilized off the posterior aspect of the omohyoid muscle, which forms the anteroinferior limit of the neck dissection.

Once the digastric tendon and the posterior edge of the mylohyoid muscle are visualized, the mylohyoid is retracted with an Army-Navy retractor so that the submandibular duct, the lingual nerve with its attachment to the submandibular gland, and the hypoglossal nerve are visualized. The submandibular duct and ganglion are ligated, and the submandibular gland is retracted out of the submandibular triangle.

At this point, the facial artery is encountered and suture-ligated. Because the artery curves around the submandibular gland, the facial artery, if not preserved, must be ligated twice (proximally and distally). If the neck dissection is part of a large extirpative procedure involving free-flap reconstruction, the facial artery is preserved for use in microvascular anastomosis.

The posterior belly of the digastric muscle is then identified inferior to the submandibular gland. This muscle has been referred to as one of several “resident’s friends” in the neck because it serves to protect several critical structures that lie just deep to it, including the hypoglossal nerve, the external carotid artery, the internal jugular vein, and the spinal accessory nerve [see Figure 4]. The posterior belly of the digastric muscle is skeletonized to the sternocleidomastoid muscle,

where it inserts on the mastoid tip. The specimen is then mobilized away from structures just inferior to the digastric muscle. The hypoglossal nerve emerges from beneath the mylohyoid muscle and passes into the neck just below the digastric muscle, looping around the external carotid artery at the origin of the occipital artery and ascending to the skull base between the external carotid artery and the internal jugular vein. Bleeding from small branches of the common facial vein that envelop the hypoglossal nerve places this structure at risk for injury. The spinal accessory nerve is often visualized just superficial or posterior to the internal jugular vein, extending posteriorly to innervate the sternocleidomastoid muscle.

Next, the fascia overlying the sternocleidomastoid muscle is grasped and unrolled medially throughout its length, starting at the anterior edge of the muscle. The fascia is removed until the spinal accessory nerve is identified at the point where it penetrates the muscle. This nerve is dissected and mobilized superiorly through fat and lymphatic tissues to the digastric muscle. Care must be taken not to inadvertently injure the internal jugular vein, which lies in close proximity

Figure 4 Selective neck dissection. The posterior belly of the digastric muscle is identified inferior to the submandibular gland. This muscle protects several critical structures just deep to it (the hypoglossal nerve, the carotid artery, the internal jugular vein, and the spinal accessory nerve). View is of a left neck dissection.

to the nerve superiorly. Tissue posterior to the accessory nerve is grasped and freed from the deep muscles of the neck, the digastric muscle superiorly, and the sternocleidomastoid muscle posteriorly. The tissue included in so-called level IIB is passed beneath the spinal accessory nerve and incorporated into the main specimen.

The sternocleidomastoid muscle is retracted, and the fascia posterior to the internal jugular vein is incised. Dissection is carried down to the deep cervical musculature and cervical nerves, which form the floor of the dissection. The specimen is retracted anteriorly. A layer of fascia is left on the deep cervical musculature and the cervical nerves to preserve innervation of the deep muscles of the neck and protect the phrenic nerve as it courses over the anterior scalene muscle.

The specimen is peeled off the internal jugular vein and removed. Dissection too far posteriorly behind the vein may result in injury to the vagus nerve or the sympathetic trunk and predisposes to postoperative thrombosis of the vein. Ligation of internal jugular vein branches should be done without affecting the caliber of the vein or giving the vessel a “sausage link” appearance, which would create turbulent flow patterns predisposing to thrombosis. Overall, gentle dissection around all vessels, with care taken to avoid pulling-related trauma, minimizes the risk of endothelial injury.

A level IV dissection may be facilitated by retracting the omohyoid muscle inferiorly or by dividing it for additional exposure. The tissue inferior to the omohyoid is mobilized and delivered with the main specimen. The lymphatic pedicle is clamped and ligated. Care is taken to look for leakage of chyle, particularly when a level IV dissection is performed on the left.

Levels II to IV

When level I is spared, a smaller incision suffices for exposure. Subplatysmal flaps are raised superiorly to the level of the submandibular gland. The inferior flap is raised, exposing the anterior edge of the sternocleidomastoid muscle. Dissection proceeds just inferior to the submandibular gland until the posterior belly of the digastric muscle is identified. The digastric muscle is skeletonized posteriorly to the sternocleidomastoid muscle and anteriorly to the omohyoid muscle, which forms the anterior limit of the dissection. The rest of the neck dissection proceeds as described for a selective neck dissection involving levels I through IV.

Complications

INTRAOPERATIVE

Most intraoperative complications may be prevented by means of careful surgical technique, coupled with a thorough understanding of head and neck anatomy. Injury to the internal jugular vein may occur either proximally or distally. Uncontrolled proximal bleeding endangers adjacent critical structures, such as the carotid artery and the hypoglossal nerve. The bleeding may be initially controlled with pressure, followed by a methodical search for the bleeding source. Internal jugular vein lacerations can often be repaired with 5-0 nylon sutures; if a laceration cannot be repaired, the vein must be ligated. Occasionally, a laceration extends up to the skull base, and the vessel cannot be controlled with clamping

and ligation. In these cases, it is acceptable to pack the jugular foramen for hemostasis.

It is important to gain distal control of the internal jugular vein before repair to prevent air embolism. Harbingers of air embolism include the presence of a sucking sound in the neck, a mill-wheel murmur over the precordium, electrocardiographic changes, and hypotension. Predisposing factors include elevation of the head of the bed and spontaneous breathing, which increase negative intrathoracic pressure and thus promote entry of air into the venous system. Injury to the internal jugular vein is more difficult to control when it occurs distally in the neck or chest at the junction with the subclavian vein. For this reason, ligation of the internal jugular vein in radical and modified radical neck dissection is typically performed 1 cm superior to the clavicle.

Opalescent or clear fluid in the inferior neck suggests the presence of a chyle fistula. Chyle fistulae generally can be prevented by clamping and ligating the lymphatic pedicle at the base of the neck. Those fistulae that occur are repaired at the time of the neck dissection. There is no benefit in isolating individual lymphatic vessels, because these structures are fragile, do not hold stitches, and are prone to tearing. A figure-eight stitch is placed along the lymphatic pedicle until there is no evidence of clear or turbid fluid on the Valsalva maneuver. Care must be taken not to inadvertently injure the vagus nerve or the phrenic nerve during repair of a chyle leak.

POSTOPERATIVE

The best treatment of postoperative complications such as hematoma and chyle leak is prevention. Hematomas, once present, are best managed by promptly returning the patient to the operating room for evacuation. Management of postoperative leakage of chyle depends on the volume of the leak. Low-volume leaks may be managed with packing, wound care, and nutritional supplementation with medium-chain triglycerides.

Wound complications (e.g., infection, flap necrosis, and carotid artery exposure or rupture) share certain interrelated causative factors. Poor nutritional status, advanced tumor stage at presentation, hypothyroidism, and preoperative radiation therapy have all been associated with wound complications. After chemoradiation therapy, the use of smaller incisions and more limited dissection of soft tissues may lower the incidence of postoperative wound problems, including persistent lymphedema and soft tissue fibrosis. Conversely, poor planning of skin incisions may increase the likelihood of wound complications such as wound breakdown, skin flap loss, and exposure of vital structures. Wound complications predispose to carotid artery rupture, the most catastrophic complication of neck dissection.

In some cases, severe edema after planned neck dissections in patients previously treated with chemoradiation may cause respiratory decompensation that necessitates tracheotomy. Postoperative internal jugular vein thrombosis is not uncommon despite preservation at the time of surgery,²⁸ and it may exacerbate facial and upper airway edema. Impaired venous outflow predisposes to increased intracranial pressure.²⁹ This may be a greater concern in patients who require bilateral neck dissections. If a radical neck dissection is performed on one side, the internal jugular vein must be preserved on the

other, or else the neck dissections must be staged. These problems are further exacerbated when the patient has undergone chemoradiation therapy before operation.

Most neck dissections result in some degree of temporary shoulder dysfunction. Patients in whom nerve-sparing procedures are performed can expect function to return within 3 weeks to 1 year, depending on the procedure performed.

Shoulder dysfunction and pain are exacerbated when nerves supplying the deep muscles of the neck are also sacrificed. All patients benefit from physical therapy, which preserves full range of motion in the shoulder while function returns.

Financial Disclosures: None Reported

8 TRACHEOSTOMY

H. David Reines, MD, FACS, and Elizabeth Franco, MD, MPH&TM

History

The word *tracheotomy* first appeared in *Libri Chirurgiae 12*, published in 1649, but it was not until Laurence Heruter, a German surgeon, reintroduced it that it became part of modern medicine. It was initially performed as a lifesaving procedure to establish an airway. Alexander the Great is reported to have used his sword to open the trachea of a suffocating soldier. The term *tracheotomy* is defined as a surgical creation of an opening in the anterior trachea that can be reversible and temporary, whereas, technically, *tracheostomy* is the formation of an opening into the trachea by suturing the edges of the opening to the skin of the neck. However, over the years, the two terms have been used interchangeably. For this document, we use the term *tracheostomy* to describe the procedure.

Indications

The indication for a tracheostomy has changed over the years. Originally, it was conceived as a method to obtain an airway for obstruction from infections, neoplasm, or trauma. The most common indications for modern tracheostomy are prolonged ventilation for respiratory failure and airway protection following traumatic brain injury with neurologic dysfunction.

Patients requiring tracheostomy or cricothyroidotomy fall into four categories:

1. Emergency for airway control, that is, airway obstruction from the epiglottitis, foreign-body aspiration, laryngeal trauma, or maxillofacial trauma
2. Semielective for patients requiring prolonged intubation or mechanical ventilation for respiratory failure or high spinal cord injury
3. Elective for airway protection, that is, traumatic brain injury, stroke, sleep apnea, or vocal cord problems
4. Elective for long-term airway access. Permanent tracheostomies are used to maintain airway access when patients undergo major head or neck dissection for tumors of the larynx and the base of the tongue.

Patients who arrive with either acute airway compromise from neck trauma or facial burns should first undergo an attempt at oral intubation, and if this fails, an emergent surgical airway is required.

Laryngoscopy should be attempted prior to performing surgical airway. If a patient arrives talking, but there is evidence of hoarseness with increasing airway compromise, the surgeon should be prepared for a surgical airway if

oral intubation is unsuccessful. When an attempt at oral intubation fails and ventilation is a problem, immediate cricothyroidotomy should be performed. A semielective surgical airway should be undertaken in a patient whose injuries may result in progressive laryngeal and cervical soft tissue edema prior to decompensation from respiratory distress. Patients with a Glasgow Coma Scale (GCS) less than or equal to 8 cannot protect their airway, and intubation should be performed immediately. If this is not possible, then a surgical airway should be considered prior to transporting the patient.

Early Tracheostomy

If the patient is ventilator dependent or has severe head injury and will need prolonged airway protection, early tracheostomy should be considered when intracranial pressure is not elevated. Early tracheostomy is defined as occurring at or before 7 days, whereas late tracheostomy occurs after 7 days. Early tracheostomy has been associated with decreased incidence of ventilator-associated pneumonia, decreased days of mechanical ventilation, decreased hospital stay, decreased intensive care unit (ICU) length of stay, and increased patient comfort. Although no study has demonstrated a decrease in overall mortality with early tracheostomy, tracheostomy does provide easier access for suctioning and allows patients to be liberated from the ventilator without the loss of an airway.

Pertinent Anatomy

The trachea lies relatively superficially in the anterior neck covered by the strap muscles midline and the platysma. The first tracheal ring is just below the cricothyroid, whereas the next three rings may lie beneath the thyroid isthmus. The sixth through seventh rings lie low in the neck and into the sternal notch [see Figure 1]. When performing a tracheostomy, knowledge of the normal and potentially abnormal vasculature is imperative. Care must be taken with a horizontal incision to avoid bleeding from injury to the anterior jugular vein. Other potential causes of hemorrhage may arise from injury to a high-riding innominate artery, a medially placed carotid artery, and the thyroid ima vessels in the midline. Tumors, hematoma, and edema can cause tracheal deviation from midline. Other anatomic variants should also be considered. An obese patient may require deeper dissection, longer instruments, and the use of an extra-long tracheostomy tube. The length of the neck and the distance from the jaw to the thyroid cartilage should also be examined. Patients with a known or potential neck injury or with kyphosis must be positioned without extension. Access to the trachea may be compromised, and plans for dissecting the thyroid isthmus should be considered.

* The authors and editors gratefully acknowledge the contributions of the previous author, Ara A. Chalian, MD, FACS, to the development and writing of this chapter.

Figure 1 Surgical tracheostomy. A transverse cutaneous incision is made that is approximately 2 to 3 cm long (or as long as is necessary for adequate exposure). The extent of flap elevation may be 1 cm or less.

Physiology

When undergoing a tracheostomy, ideally, the patient should be adequately ventilated and hyperoxygenated in anticipation of a period of apnea during tracheostomy tube placement. An oxygen saturation of 100% and a normal pH and carbon dioxide tension (P_{CO_2}) are desirable at the start of an elective tracheostomy. Use of 100% oxygen during the procedure will help maintain adequate oxygenation throughout the procedure. When an emergency cricothyroidotomy or tracheostomy is necessary, an attempt should be made to preoxygenate and ventilate.

Counseling and Informed Consent

The patient, the family, or both should be advised of the risks and benefits of a tracheostomy. Commonly discussed issues, including pain, mortality, and the range of possibilities of early and late complications (see below), should be on the consent form. A tracheostomy should be proposed as the best option for the patient requiring prolonged mechanical ventilation or airway protection. Tracheostomy contributes to patient comfort, allowing improved oral care, oral alimentation, and speaking as well as the potential for earlier liberation from the ventilator.

Site of the Procedure

Elective open tracheostomy requires good lighting and electrocautery. Some may find open tracheostomy in the ICU

more ergonomically difficult than in the operating room (OR) because the patient is on a hospital bed; however, finding OR time and transporting the patient may be inconvenient. Several studies comparing bedside open to percutaneous tracheostomies find the techniques to be essentially equivalent in outcome with the open technique and possibly lower in cost. Percutaneous tracheostomy is most commonly performed at the bedside, in the ICU, and does not require the same lighting or instrumentation and nursing availability that an open tracheostomy does. A cricothyroidotomy is frequently performed in the trauma bay, although it may be executed anywhere and requires the least amount of instrumentation. Emergency tracheostomy and cricothyroidotomy are frequently not performed in the OR.

Anesthesia

Anesthesia can frequently be given as conscious sedation and/or local anesthesia with epinephrine. Paralysis should be avoided when possible in a patient with any spontaneous breathing.

Patient Positioning

Extension of the neck is desirable; however, if the patient has a known or potential cervical spine injury, operation in the neutral position is necessary. When possible, the patient should be placed on an operating table with a shoulder roll and a foam pad (donut) under the head. When the neck can be extended, the head rest of the surgical bed can be lowered and the patient placed in a 30° head elevation position to decrease venous pressure. Extending the head allows better palpation of the landmarks. If cervical spine precautions are necessary, the posterior portion of the cervical collar should remain in place and the head stabilized by a team member. Another alternative is to stabilize the neck with bilateral head rolls with tape over the forehead and chin extending across the bed.

Operative Techniques

EMERGENT SURGICAL AIRWAY

Cricothyroidotomy

Cricothyroidotomy is generally performed for emergent control of the airway. Inability to secure an airway, especially with severe facial trauma, requires immediate access to the trachea. A cricothyroidotomy can be performed rapidly and does not risk the anatomic problems of a tracheostomy because the cricothyroid membrane is thin and closest to the skin directly under the thyroid membrane. If a #5 or #6 tracheostomy tube is not available, an endotracheal tube can be introduced for immediate airway access.

Transtracheal Needle Ventilation and Oxygenation

Transtracheal needle access also can be used in emergency situations. A large-bore 12- or 14 gauge angiocatheter or a pulmonary artery catheter introducer sheath is placed through the cricoid membrane and attached to oxygen tubing with the capability of providing oxygen at 50 psi. A hole in the tubing is finger-occluded and intermittently opened to allow for ventilation. Adequate ventilation can be provided for

20 to 30 minutes. This method is best used as a bridge while awaiting the proper equipment and support for an orotracheal or surgical airway.

OPEN TRACHEOSTOMY

Steps

1. *Incision of the skin.* The patient should be assessed for a high-riding innominate artery, abnormally placed vessels, and tracheal deviation. Incision can be made either vertically or horizontally. The horizontal scar heals better than the vertical scar. However, visualization, especially if the neck cannot be extended, is frequently easier in a vertical incision. Damage to the anterior jugular veins likewise is less likely with a vertical incision. In an emergency, a longer vertical incision can facilitate exposure while avoiding the subplatysmal anterior jugular veins [see Figure 2]. In general, the incision should be made midway between the cricoid cartilage and the sternal notch. The size of the incision is up to the individual surgeon. However, a minimum of 2 to 2.5 cm is desirable.

Subsequent dissection must be performed perpendicular to the trachea. A common mistake when dividing the subcutaneous tissue is to deflect in a slightly oblique fashion, arriving lower in the trachea than anticipated.

2. *Retracting the strap muscles.* The midline raphe is divided and an assistant with Senn or Army-Navy retractors or with a self-retracting retractor then retracts the strap muscles laterally. Undermining should be minimized to decrease the potential creation of dead-space areas. In the case of a malignant neoplasm overlying the thyroid compartment, the anatomic landmarks may be less clear. In such a case, palpation of the thyroid cartilage and

dissecting caudally are helpful. Care must be taken, especially in women, to palpate the thyroid and not the hyoid cartilage [see Figure 3].

3. *Dissection of the thyroid gland.* The thyroid isthmus frequently lies in the field of dissection. Because its size and thickness vary greatly and can vary from 5 to 10 mm in vertical dimension, dissection of this can be undertaken, and, in many cases, immobilizing the trachea and retracting the isthmus either superiorly or inferiorly to place the tracheal incision in the second or third tracheal interspace can be accomplished [see Figure 4]. However, if the isthmus is a problem, especially in cases where the neck cannot be extended, it can be divided and the edges ligated either with ties or with a Harmonic scalpel. When there is an isthmus nodule, the isthmus should be removed for diagnostic and therapeutic purposes. Recurrent laryngeal nerves should not be directly in the operative field and are rarely at risk as long as one stays in the midline anterior on the trachea. If significant deviation of the trachea is noted, the nerves may be injured. Because the blood supply to the trachea is laterally based, one should not encounter them. However, a thyroid ima vessel is frequently noted in the lower portion of the isthmus, and this may need to be ligated prior to dissection.
4. *Incision of the trachea.* Tracheostomy should be performed with a sharp blade. The pretracheal tissues may be coagulated with a bipolar electrocautery. The opening of the airway may bring volatile gasses into the operative field; therefore, monopolar electrocautery should be avoided if volatile gasses are in use. Several types of incisions are possible:

Figure 2 Surgical tracheostomy. Retractors are placed, the skin is retracted, and the strap muscles are visualized in the midline. The muscles are divided along the raphe and then retracted laterally.

Figure 3 Surgical tracheostomy. With the strap muscles retracted, the thyroid isthmus is visualized, and the inferior (or superior) edge of the isthmus is dissected down to the trachea. The isthmus is then retracted superiorly (or inferiorly) or divided to permit visualization of the trachea before the tracheal incision is made.

Figure 4 Surgical tracheostomy. A tracheostomy is made either between the second and third tracheal rings or between the third and fourth rings. A Björk flap (*inset*) may be created by extending the ends of the tracheostomy downward through the next lower tracheal ring in an inverted U shape.

- a. *Linear incision.* This transverse incision is made either between the second and third rings or the third and fourth rings. Stay sutures are then placed superiorly and inferiorly around the tracheal rings [see Figure 5].

Figure 5 Surgical tracheostomy. The tracheostomy tube is inserted into the tracheal opening from the side, with the faceplate rotated 90° so that the tube's entry into the airway can be well visualized.

- b. *T-type incision.* This incision is a combination of a vertical incision that crosses the second ring and forms a “T” with a transverse incision below the third tracheal ring. Stay sutures are placed laterally and allow for controlled opening of the trachea with a tracheostomy spreader.
- c. *Tracheal window.* Although a tracheal window with removal of a portion of the third tracheal ring has been performed, this is more difficult and may not heal as rapidly as a ring-preserving incision.
- d. *Björk flap.* A Björk flap is an inferiorly based U-shaped flap that incorporates the ring below and the tracheal incision [see Figure 4]. A U-type incision is made from the third tracheal ring through the second tracheal ring, and the second tracheal ring is then retracted inferiorly and sutured with a dissolvable suture as high in the neck as possible to the skin. The theoretical justification for this is to keep the tracheal incision close to the skin edges in the instance of tracheostomy tube displacement, to ensure ease of airway access. This flap suture can be released 3 to 5 days after creation once the tract has been established or after the first tracheostomy change.
5. *Stay sutures.* Stay sutures using a 2-0 nonabsorbable suture on a UR6 needle can be placed either laterally or superiorly and inferiorly. These help stabilize the tracheostomy during the procedure. The sutures are then taped to the chest and labeled so that they will not be inadvertently removed. Stay sutures may provide access to a fresh tracheostomy if the tracheostomy tube becomes dislodged in the immediate postoperative period. These sutures are left in place until the first tube change.

In adults, a number 8(outside diameter [OD]) or 6(OD) tube is preferable. If there is significant edema or obesity, the use of an extra-long tube is desirable. If a tracheostomy tube is not available, a standard endotracheal tube can be used to intubate the neck. Remember when trimming the tube to spare the pilot balloon.

PERCUTANEOUS TRACHEOSTOMY

Percutaneous tracheostomy was first described over 50 years ago, but the availability of a dilational percutaneous tracheostomy kit prompted widespread use in the 1990s. In many centers, this has become the method of choice for tracheostomy. Although initial contraindications included morbid obesity, inability to extend the neck as in potential cervical spine injuries, short neck, enlarged thyroid isthmus, and previous tracheostomy, these have been disproven with increasing experience. A benefit of the percutaneous approach is the ability to perform the procedure at bedside in the ICU, reducing OR costs and scheduling conflicts. The percutaneous approach has been championed for its ease of performance at the bedside in the ICU; however, several studies comparing cost and personnel use demonstrate open bedside tracheostomy to be more cost-effective with equivalent complications and safety outcomes. The long-term cosmetic effects of percutaneous tracheostomy appear to be better than those of the open technique.

The choice between percutaneous and open tracheostomy remains a decision best left to individual centers.

Operative Technique

Equipment and personnel The personnel necessary for the procedure are a respiratory therapist, a critical care nurse, a surgeon, and a bronchoscopist to safely perform a percutaneous tracheostomy. The equipment required is a bronchoscope and a percutaneous dilation tracheostomy kit. Surgical instruments for an open tracheostomy should be readily available. Maximum sterile barriers are employed, including sterile gown, gloves, and drapes. All participating personnel must wear mask and head covers.

Procedure

1. *Incision.* Once conscious sedation is initiated, the subcutaneous tissue is infiltrated with local anesthetic 1 cm caudal to the cricoid cartilage. A 1 to 1.5 cm incision is made either in a horizontal or a vertical fashion. The subcutaneous tissue is then bluntly dissected using a hemostat to spread the tissue down to the level of the trachea.
2. *Bronchoscopy.* The bronchoscope is advanced to the tip of the endotracheal tube. With the surgeon providing one-finger ballottement at the level of the first or second tracheal ring, the endotracheal tube is slowly withdrawn while maintaining the bronchoscope at the tip of the tube until one-to-one ballottement is appreciated. Every step of the procedure involving instrumentation of the trachea is preferably performed under direct bronchoscopic visualization.
3. *Transcutaneous tracheostomy.* The introducer needle is advanced through the incision at the level where one-to-one ballottement was appreciated. Constant aspiration of the syringe and direct bronchoscopic visualization immediately identify the entrance into the trachea. Once the needle is noted to be in a good position, the guide wire is introduced again under direct bronchoscopic visualization.
4. *Dilation.* Using a modified Seldinger technique, the needle is removed and a stiff conical dilator is introduced and removed. The tract is then dilated with the largest conical dilator to the level marked for the skin. The dilator is removed and fully introduced three times. The tracheostomy tube is then introduced over the snugest fitting dilator. Once the tracheostomy tube is in place, the guide wire and dilator are removed. Often the endotracheal tube must be withdrawn a short distance to allow for serial dilation and introduction of the tracheostomy tube.
5. *Confirmation of placement.* Once the tracheostomy tube is in place, the bronchoscope is withdrawn from the endotracheal tube and introduced through the tracheostomy tube to confirm placement within the trachea. The endotracheal tube is kept in place until confirmation is complete. The tracheostomy tube is then secured with sutures from the faceplate to the skin and tied in place.

Tracheostomy Management

Tracheal sutures are removed on postoperative day 7. If the patient is on minimal ventilator settings or liberated from the ventilator, the tracheostomy tube is downsized. Once the patient is liberated from the ventilator, the tracheostomy tube cuff is deflated and the patient is placed on humidified air or oxygen. The humidified air can be delivered via a

tracheostomy collar or tracheostomy tube. A tracheostomy collar allows more patient freedom and less torque than a T tube when frequent suctioning is not required. Speech pathology consultation should be obtained for swallowing evaluation and speaking valve placement versus capping the tracheostomy tube. The approach depends on the patient's mental status and suctioning requirements. Once the patient is tolerating either tracheostomy tube occlusion or a speaking valve for greater than 24 hours and managing his or her own secretions, the tracheostomy is removed. In preparation for decannulation, the patient should be suctioned and a replacement tracheostomy with a stylet should be available in case of sudden respiratory decompensation. An occlusive dressing is left in place for 24 hours. Generally, no further dressing is required afterward.

Complications

Reported complication rates from tracheostomy range from 5 to 31%, with an average of nearly 12%. Major complications range from 2 to 6%. Mortality is extremely low (0.5%).

EARLY COMPLICATIONS

Displacement

The most dangerous complication is early accidental displacement or decannulation. This can occur when moving the patient to the ICU or recovery room and when patients are turned for care or x-rays in the ICU in the first 5 to 7 days after placement. A loosely tied tracheostomy or one placed in a precarious position can be dislodged, resulting in the inability to ventilate and oxygenate. If this is suspected, the patient should immediately be placed supine and an attempt at ventilation should commence. If the patient cannot be ventilated, an attempt to replace the tube should be tried if stay sutures or a Björk flap is present. Emergency oral intubation should be performed if the attempt fails. Multiple attempts to replace the tube can result in a false passage. The tracheostomy can then later be replaced via the same incision with the proper light and proper retraction. A new tracheostomy tube should be available in the room or above the bed for all patients who have had a fresh tracheostomy.

Pneumomediastinum/Pneumothorax

Pneumomediastinum can occur, especially with a low tracheostomy or if a false passage is created. Pneumothorax is a rare (< 2%) complication that can occur especially in children, in whom the cupola of the lung may ride high. Pneumothorax can also occur in patients who require high ventilatory pressures or who cough vigorously during the procedure. A low tracheostomy and deep dissection potentially increase the risk of pneumothorax.

Bleeding

A small amount of blood via the wound or tracheostomy immediately following the procedure is not alarming. However, the persistence of blood around the trachea implies venous bleeding from either the skin, subcutaneous tissues, or thyroid gland. In general, this can be controlled with gentle packing and the use of a bioabsorbable hemostatic agent. If bleeding continues, the patient should be taken to the OR if possible and reintubated under ideal light and retraction;

the tracheostomy should be removed and the bleeding controlled with cautery or sutures if necessary. If hemorrhage is demonstrated via the tracheostomy tube, early careful bronchoscopy should be performed to ascertain the site of bleeding. Significant bleeding from the tracheostomy is usually a late complication and may be related to a tracheoinnominate fistula (see below).

Infection

Tracheostomy infections requiring treatment are much less common than one would imagine, considering the contamination of the bronchial/tracheal tree in many patients who have been intubated for a period of time. The majority of infections can be treated with local wound care, although deep infections from *Staphylococcus aureus* and *Pseudomonas aeruginosa* may require antibiotics and removal of sutures. Placing tracheostomies through burn eschar presents a separate problem.

Acute Obstruction

The most common cause for acute obstruction of a tracheostomy is dislodgment. If that is not the case, the tracheostomy may have accumulated blood or mucus, which can clog the airways. To avoid this, humidified oxygen should always be administered, and gentle careful suctioning should be initiated by experienced personnel. The inner cannula should be removed and examined. Occasionally, bronchoscopy will be necessary to remove and irrigate mucus plugs.

Negative Pressure Pulmonary Edema

A rare complication of upper airway obstruction may occur after a tracheostomy is performed for airway obstruction. Patients generating large negative pressure against resistance, which is suddenly released, can experience a noncardiogenic pulmonary edema. The patient becomes hypoxic, develops rales in the lungs, and can demonstrate pink frothy pulmonary edema via the tube. A chest x-ray may demonstrate bilateral pulmonary edema. This process is usually self-limited and responds to positive end-expiratory pressure (PEEP) and positive pressure ventilation.

LATE COMPLICATIONS

Late complications of tracheostomy are often attributable to the cuff, either from the tracheostomy tube or from the endotracheal tube in place prior to tracheostomy. Complications attributable to cuff injuries are less common now than previously as a result of improvement in technology allowing for lower-pressure cuffs, but they still occur in patients who undergo prolonged endotracheal intubation.

Tracheostomy cuff pressures should be measured daily or more often to prevent tracheal necrosis. X-rays demonstrating a dilated cuff in the trachea require assessment of the tube, cuff, and trachea.

Subglottic Tracheal Stenosis

Tracheal stenosis has a reported incidence of 4 to 18%. Stenosis is associated with a longer hospital stay and prolonged time to tracheostomy. Dyspnea and stridor result when tracheal stenosis is greater than 50% of tracheal diameter. In suspected tracheal stenosis, referral to a specialist for evaluation either by computed tomography (CT) or rigid laryngoscopy is essential for diagnosis. Once the diagnosis is confirmed, treatment may require tracheal reconstruction.

Tracheal Granulation

Tracheal granulation may cause bleeding or occlusion of the tracheostomy tube if a flap of granulation tissue is elevated on exhalation. Granulation tissue may mimic tracheal stenosis. This complication is often easily treatable with removal of the tracheostomy tube. Occasionally, resection of the granulation tissue is necessary.

Vocal Cord Dysfunction

Vocal cord dysfunction occurs in less than 2%, whereas voice changes, including hoarseness and weakness, occur in 10 to 20% of patients. In cases of bilateral vocal cord paralysis, a tracheostomy is necessary until the paralysis resolves. Most complaints of vocal changes are considered minor by patients.

Tracheoesophageal Fistula

Tracheoesophageal fistula occurs in less than 0.3% of patients following tracheostomy. It can occur if a puncture is made into the posterior trachea or a cuff erodes into the esophagus. The combination of a tracheostomy tube and a stiff nasogastric tube in the esophagus increases the risk of this complication. Symptoms include aspiration and persistent cuff leak around the tracheostomy. Persistent tracheobronchitis or pneumonia may also be present. A swallow study with the cuff deflated or CT and panendoscopy will demonstrate the defect. Definitive therapy is usually necessary.

Tracheoinnominate Fistula

Tracheoinnominate fistula has a reported incidence of 0.4 to 4.5% and presents initially as "sentinel bleeding" that usually develops within the first month following the procedure. Mortality between 50 and 75% has been reported. Risk factors include a low (below the third ring) tracheostomy, caudal migration from leverage on the tube, and the presence of a more cephalad-coursing innominate artery. An attempt to visualize the site of bleeding should be undertaken. If hemorrhage is significant, hyperinflate the cuff and try to compress the vessel against the posterior sternum. If this is unsuccessful, oral intubation should be performed. The tracheostomy tube must be removed and replaced with digital pressure through the tracheostomy to tamponade the bleeding en route to the OR. Often the upper extremity of the person responsible for maintaining digital pressure is prepared into the operative field in preparation for median sternotomy.

Tracheocutaneous Fistula

Rarely, the tracheostomy wound does not completely close in 24 to 48 hours. Granulation tissue may be treated topically with silver nitrate with good success. Occasionally, the tracheostomy site must be surgically closed in layers for a nonhealing tracheocutaneous fistula.

Scar

Cosmetic results vary following tracheostomy. Ten to 15% of patients consider scar revision of the tracheostomy site.

Financial Disclosures: None Reported.

9 THYROID DISEASES

Karen R. Borman, MD, FACS, and Jennifer L. Rabaglia, MD*

Approach to the Patient with Thyroid Disease

The thyroid plays a central role in normal metabolic and homeostatic processes, including thermomodulation, protein synthesis, carbohydrate and lipid metabolism, and modulation of adrenergic activity. A normal thyroid weighs 15 to 25 g and is firm, mobile, and smooth to palpation. The thyroid contains two distinct, physiologically active cell types. Follicular cells are responsible for thyroid hormone synthesis, whereas parafollicular or C cells produce calcitonin. Patients are most often referred to the surgeon for control of hyperthyroidism or for treatment of euthyroid nodular disease.

APPROACH TO THE PATIENT WITH HYPERTHYROIDISM

The symptoms of thyroid hormone overproduction are numerous and often nonspecific, including palpitations, heat intolerance, weight changes (gain or loss), increased appetite, poor concentration, decreased libido, and irregular menses. The diagnosis of hyperthyroidism is definitively established by thyroid function testing (TFT); thyroid-stimulating hormone measurement (TSH, thyrotropin) is the single most useful test. TSH normally ranges between 0.3 and 3.0 mU/L; values less than 0.3 indicate hyperthyroidism (excess thyroid hormone causing decreased TSH secretion), and values > 3.0 suggest hypofunction (low levels of circulating thyroid hormone stimulating increased TSH secretion). Free thyroxine (T_4) and triiodothyronine (T_3) levels can provide further confirmation. Total T_4 and T_3 levels are influenced by serum protein derangements and must be interpreted with caution. Thyroglobulin (Tg) and calcitonin determinations are not useful for diagnosing hyperthyroidism.

DIFFERENTIAL DIAGNOSIS

Potential etiologies for hyperthyroidism are numerous, but relatively few lead to surgical referrals. Thyroidectomy as a treatment option is largely confined to three entities: diffuse toxic goiter (Graves disease), toxic nodular goiter (TNG; Plummer disease), and solitary hyperfunctioning nodule. Other forms of hyperthyroidism most often respond to medical management and/or withdrawal of the inciting agent (e.g., amiodarone) while the underlying thyroiditis resolves [see Table 1].

* The authors and editors gratefully acknowledge the contributions of the previous authors of "Thyroid and Parathyroid Operations," Wen T. Shen, MD, Gregg H. Jossart, MD, FACS, and Orlo H. Clark, MD, FACS, to the development and writing of this chapter.

Table 1 Etiologies of Hyperthyroidism

Disease	Predominant Treatment
Iodine induced (jodbasedow)	Medical
Subacute thyroiditis (de Quervain)	Medical
Chronic lymphocytic thyroiditis (Hashimoto thyroiditis)	Medical (surgical for compressive symptoms)
Postpartum thyroiditis	Medical
Drug induced (e.g., amiodarone)	Medical (rarely surgical)
Struma ovarii	Surgical (resect ovarian teratoma)
Graves disease	Medical or surgical
Toxic nodular goiter (Plummer disease)	Surgical or medical
Solitary hyperfunctioning nodule	Surgical; rarely medical

CLINICAL EVALUATION

History and Physical Examination

A thorough history may raise considerations of thyroiditis (e.g., amiodarone, pregnancy, iodinated contrast agents) and lead to reconsideration of nonsurgical management. Previous or ongoing treatment with thyroxine or antithyroid medications (ATMs) is noteworthy, along with review of recent TFT results. Factors that could influence treatment choices (e.g., iodine allergy, comorbid diseases) should be identified. Adrenergic symptoms (e.g., palpitations, tremor) are valuable in assessing antithyroid treatment response and readiness for operation. Compression symptoms (dysphagia, nocturnal dyspnea) are more likely with TNG than Graves disease or solitary toxic nodule (STN). Dysphonia is extremely rare with benign disease and should be definitively evaluated before thyroidectomy is recommended.

Examination of the thyroid begins with observation of the neck for goiter, including size and symmetry. Palpation may discriminate the smooth, soft, diffuse Graves gland from the firm, multinodular toxic goiter or the STN. Tenderness to palpation is most consistent with thyroiditis, as is bilateral lymphadenopathy. Unilateral, hard, or fixed cervical or supraclavicular adenopathy should prompt evaluation as outlined below for euthyroid nodular disease. Substernal extension of the goiter and cervical tracheal deviation should be noted when present. A solitary or dominant nodule should be characterized as to its location, size, and mobility. Physical examination should also focus on other signs of hyperthyroidism, including Graves ophthalmopathy (lid lag, lid retraction, proptosis, exophthalmos) and adrenergic excess (tachycardia, bilateral fine tremor of the hands). General medical status should be assessed as for any potential preoperative patient.

Imaging

Thyroid scintigraphy reliably characterizes the hyperthyroid processes most often referred to surgeons and should precede any other form of imaging. Technetium pertechnetate (Tc-99m) scanning is rapid and produces sharper images at lower cost than iodine-123 (^{123}I). ^{123}I scintigraphy is superior when precise uptake quantification is required (before radioactive ^{131}I treatment) or when better bone penetration is necessary (substernal goiter).¹ Graves disease appears as homogeneous radionuclide uptake. An enlarged, heterogeneous gland with two or more areas of increased uptake surrounded by areas of normal or decreased uptake is typical of TNG. An STN is confirmed when a single, high-uptake (“hot”) focus is seen against a suppressed background. Computed tomography (CT) and magnetic resonance imaging (MRI) have limited utility in hyperthyroidism other than for assessment of substernal goiters, and iodinated contrast administration will interfere with any subsequent ^{131}I treatment. Once the etiology of the hyperthyroidism is established, treatment options may then be considered. TNG and STN are preferentially treated operatively, whereas the algorithm for Graves is a bit more complex; ultrasonography (US) and fine-needle aspiration (FNA) may be indicated to exclude malignancy if nonoperative treatment is chosen.

TREATMENT CONSIDERATIONS

Initial Therapy

Medical management for control of symptoms and signs of hyperthyroidism precedes surgical treatment. ATMs and beta blockers are the most commonly used agents. The thionamides propylthiouracil (PTU) and methimazole limit thyroid hormone synthesis by disrupting organification of iodine. PTU also inhibits peripheral conversion of T_4 to the metabolically more active T_3 . Minor side effects (pruritis, fever, gastrointestinal disturbances, and arthralgia) occur in 5 to 25% of patients receiving thionamides, and agranulocytosis affects 0.2 to 0.5% of patients receiving either medication.² Rare cases of fulminant hepatic failure and autoimmune vasculitis have been associated with PTU alone.²⁻⁴ Beta blockers (atenolol, propranolol) may be added to ATM for more rapid control of severe adrenergic symptoms when present. Treatment efficacy is monitored by TFTs and clinical evaluation (resolution of tachycardia and tremor). Most patients are rendered euthyroid within 6 weeks of treatment initiation; virtually all are euthyroid at 3 months. PTU is often chosen over methimazole during pregnancy as methimazole is more apt to cross the placenta and has been linked to fetal scalp aplasia cutis.

Preoperative Therapy

Achieving euthyroidism markedly reduces the chance of thyrotoxicosis and thyroid storm intra- or postoperatively. Preoperative treatment goals include normalization of TFTs, a resting heart rate of 60 to 70 beats per minute, and resolution of tremor. In Graves disease patients, inorganic iodine administration in the form of Lugol solution (3 to 5 drops t.i.d.) or saturated solution of potassium iodide (SSKI; 2 to 3 drops t.i.d.) may decrease the size and vascularity of the gland when given for 7 to 10 days immediately preoperatively. Beta blockade alone supplemented by inorganic iodine is somewhat less effective but is rarely used in urgent clinical circumstances or for patients intolerant of thionamides.

Graves Disease

Graves disease is the leading cause of hyperthyroidism in the United States, comprising about 70% of cases. Women between the ages of 20 and 50 years are most commonly affected.³

There are three effective, long-term treatments for Graves disease: prolonged ATM administration, radioactive iodine (RAI), and thyroidectomy. Factors influencing treatment choice include overall patient status (age, gender, comorbidities, life expectancy); thyroid findings (goiter size, dominant nodule, compression symptoms); health care system characteristics (access to physicians, medications, and laboratory testing); and patient preference.

Prolonged ATM administration Although common in Europe and Asia, this treatment is not often chosen in the United States, perhaps linked to the rare but potentially life-threatening side effect profile of thionamides. This approach also requires a prolonged medication trial (12 to 24 months), and patients often find this less palatable when more rapidly acting treatments with higher success rates are available. Remission (euthyroidism for at least 1 year posttreatment) is achieved initially in approximately 50% of cases, but this success rate declines to 30% at 10 years.^{2,3,5} Negative predictors of remission include large goiter, severe biochemical disease, high serum ratio of T_3 to T_4 , male gender, multiple relapses, and very high TSH receptor antibody titers.^{2,5} Remissions are more common in adults than in children. Prolonged ATM administration should be considered when life expectancy is limited. Here methimazole has the advantage of twice-daily dosing versus PTU, which is given three to four times per day. Patients who fail to achieve remission or who relapse can be salvaged with RAI or surgery.

Radioactive iodine RAI is the definitive management of choice for Graves disease in the United States. Approximately 60% of patients are euthyroid within 6 to 8 weeks after a single oral dose of 5 to 15 mCi, and nearly all the remaining patients become euthyroid within several months.⁴ Hyperthyroidism persists or recurs in 5 to 25% of cases and is dose dependent. Posttreatment hypofunction is also dose dependent. The risk of hypothyroidism is 20% within the first year and 3 to 5% per year thereafter. Thus, TFTs must be followed lifelong in all patients treated with RAI. Acute adverse reactions are uncommon after RAI administration. Pain secondary to radiation thyroiditis and nausea are reported most often. Because RAI treatment can trigger thyrotoxicosis, pretreatment with ATM before RAI administration may be appropriate for patients who are elderly or have concurrent heart disease. An exceedingly rare but more serious complication is hypoparathyroidism, which can be detected promptly by monitoring serum calcium.

RAI may not be the preferred treatment for some subgroups of patients with Graves disease. Although little credible evidence supports a generalized oncogenic effect of RAI, parental concerns about future cancers may prompt a choice for prolonged ATM administration or surgery in Graves disease in children and adolescents. RAI may exacerbate eye manifestations in patients with Graves ophthalmopathy,

particularly in smokers or when hyperthyroidism is severe.^{6,7} Concurrent glucocorticoid administration minimizes this risk,^{6,7} although moderate to severe ophthalmopathy remains a relative contraindication to RAI therapy, and surgery may be preferred in cases where eye findings of Graves disease are clinically overt. Pregnancy and lactation are absolute contraindications to RAI because ¹³¹I crosses the placenta and is secreted into breast milk. Women should defer pregnancy for 6 to 12 months after receiving RAI to allow for stabilization of maternal thyroid function and to prevent transplacental passage of residual radioisotope and subsequent fetal hypothyroidism. RAI therapy is also contraindicated in patients who are allergic to iodine.

Surgery Surgical intervention provides rapid normalization of thyroid function with the lowest rate of recurrent hyperthyroidism while avoiding both the potential risks of prolonged ATM administration and the theoretical risk of ionizing radiation. **Surgical treatment is preferred for Graves disease patients with relative or absolute contraindications to RAI, as outlined above, as well as in patients with compressive symptoms and those with concurrent suspicious or indeterminate nodules.** Operation also is favored in patients for whom RAI is less likely to be effective, including patients with large goiters, severe biochemical disease, a high serum ratio of T₃ to T₄, male gender, or very high TSH receptor antibody titers. Graves ophthalmopathy frequently stabilizes and sometimes regresses after operation.^{8,9} In some cases, patients may choose surgery to avoid ionizing radiation, to simplify family planning, or to minimize the duration of thyrotoxicosis.

Recommendations about the optimal extent of thyroidectomy for Graves disease have evolved over time. Bilateral subtotal resection was historically advocated for its safety profile and control of hyperthyroidism with the potential for euthyroidism without medication. However, estimation of tissue remnant size that will avoid hypothyroidism while minimizing recurrent hyperthyroidism may be difficult. **Recent studies suggest similar complication rates following subtotal and total resections, whereas cure rates are substantially higher after total thyroidectomy.^{8,10,11}** When performed by surgeons with appropriately low morbidity (recurrent laryngeal nerve injury less than 1% and permanent hypoparathyroidism less than 3%^{8,10}), total thyroidectomy is now favored over lesser resections.

Toxic Nodular Goiter

Much less prevalent than Graves disease, TNG accounts for about 25% of all cases of hyperthyroidism in the United States. TNG is uncommon in patients under 50 years of age but is the most common cause of hyperthyroidism in the elderly.¹² TFT abnormalities are similar to those in Graves disease, although a higher proportion of patients with TNG will have T₃ thyrotoxicosis. Treatment options include ATM, RAI, and surgery.

Prolonged ATM administration TNG results from thyroid hormone production by multiple autonomously functioning nodules without the potential for spontaneous

remission. Definitive management of TNG by ATM therefore requires lifelong ATM administration. Because of rare but sometimes life-threatening adverse reactions to the thionamides, only TNG patients with limited life expectancies are suitable for primary ATM treatment.

Radioactive iodine Iodine uptake is lower and less uniform in TNG than in Graves disease, making effective RAI dosing less predictable. Substantially higher initial doses are necessary, and up to 20% of patients require at least one additional RAI treatment.² Thus, patients may experience more side effects, including prolonged xerostomia and xerophthalmia, oral ulcers, and sialadenitis.¹³ As with Graves disease, the time to euthyroidism is prolonged, and the risk of posttreatment hypothyroidism remains substantial. RAI shrinks the gland in less than half of patients, and radiation thyroiditis may cause serious, symptomatic thyroid edema. As a result, RAI is particularly unsuited for TNG patients with large or substernal goiters or with pretreatment compression symptoms. RAI for treatment of TNG is typically reserved for patients who are poor surgical candidates or those with small, asymptomatic goiters who refuse surgery.

Surgery Thyroidectomy is the treatment of choice for TNG. Surgery allows for rapid control of hyperthyroidism, relief of compressive symptoms, and histologic examination of any dominant or suspicious nodules and avoids any long-term side effects of ionizing radiation. Total thyroidectomy is favored when performed by surgeons with acceptable complication rates and confers the advantages of easy titration of thyroid replacement and a nonexistent recurrence rate. Inorganic iodine (Lugol, SSKI) generally is not given preoperatively in this setting as the variable and unpredictable iodine uptake by TNG raises the risk of triggering acute thyrotoxicosis.

Solitary Toxic Nodule

STN causes less than 5% of all cases of hyperthyroidism in the United States. The frequency of STN is higher in women

and increases with age. STNs are usually palpable on physical examination as thyrotoxicosis is rare when nodules are under 3 cm in diameter.² Like TNG, STN can be associated with T₃ toxicosis and normal T₄ levels. Treatment choices include ATM, RAI, and surgery.

Prolonged ATM administration Excess thyroid hormone secretion by the autonomously functioning STN will recur after ATM withdrawal. Definitive management of STN by lifelong ATM treatment is an option of last resort because of the rare but sometimes life-threatening adverse reactions to the thionamides, and this is indicated only for patients with limited life expectancy.

Radioactive iodine RAI can be effective definitive treatment for STN but usually is reserved for very-high-risk surgical candidates and for patients who refuse operation. The differential RAI uptake of the surrounding suppressed gland compared with the STN can confound RAI dosing.

Intense RAI concentration by the STN itself exposes the adjacent normal thyroid to potentially oncogenic levels of ionizing radiation, with subsequent risk of thyroid neoplasia.

Surgery Thyroidectomy is the treatment of choice for STN. Resection of the affected thyroid lobe promptly controls hyperthyroidism in patients with STN and relieves any symptoms associated with these relatively large nodules. The risks of operation are quite low because lobectomy plus isthmusectomy is sufficient in most cases. When the contralateral remaining lobe is normal, long-term T₄ supplementation is usually unnecessary.

Approach to the Patient with Euthyroid Nodular Disease

Thyroid nodules are very common and represent a wide spectrum of thyroid disease, both benign and malignant [see Table 2 and Table 3]. Palpable disease is present in 5 to 7% of women and 1 to 2% of men, whereas cervical US reveals subclinical nodular disease in up to 67% of patients.¹⁴ Most patients with nodules are clinically and biochemically euthyroid. Surgical referral is usually targeted at

symptomatic relief in bulky benign disease, definitive diagnosis for indeterminate lesions, and definitive therapy for malignancy. Although the incidence of thyroid cancer has doubled since 1973,¹⁴ 85 to 96% of palpable and subclinical nodules are benign. The rate of malignancy varies with factors including age, gender, family history, and radiation exposure. Screening for thyroid cancer is not cost-effective in the general population but is appropriate for some high-risk groups (e.g., multiple endocrine neoplasia [MEN] kindreds, after substantial radiation exposure). When considering treatment options, near-total (residual tissue < 1 g) and total (removal all visible thyroid) thyroidectomy will be used interchangeably. Subtotal resection refers to residual tissue more than 1 and less than 5 g.

DIFFERENTIAL DIAGNOSIS

The clinical challenge of euthyroid nodular disease is to reliably identify the small subset of patients with substantial likelihood of malignancy while avoiding the risks of surgery for the vast majority of patients with benign disease. Most thyroid nodular disease is more common in women and occurs in middle age, although anaplastic thyroid cancer (ATC), lymphoma, and sporadic medullary thyroid cancer (MTC) peak somewhat later.¹⁵ Papillary (PTC) and follicular (FTC) thyroid cancers are often grouped together as well-differentiated thyroid cancer (WDTC).

CLINICAL EVALUATION

History and Physical Examination

A palpable solitary or dominant nodule should lead to documentation of duration, changes in size, associated symptoms, exposure to ionizing radiation, prior thyroid disease, or prior therapy with T₄. Recent TFT results should be reviewed. Bearing in mind that most WDTCs are slow-growing and asymptomatic, rapid growth with associated symptoms suggests an aggressive process, such as ATC or lymphoma.¹⁶ Dysphagia and dyspnea are more common with multinodular goiter (MNG), whereas pain and hoarseness should heighten concerns for malignancy. Hashimoto disease raises the chance of lymphoma, and exposure to ionizing radiation, especially in childhood or adolescence, increases the likelihood of PTC. Family history should target a history of familial endocrinopathy or other hereditary tumor syndromes linked to thyroid disease, especially in the setting of suspected MTC¹⁷ [see Table 4]. A history of prior neck surgery or irradiation should be carefully documented.

On examination, the neck is observed for visible nodule or goiter. Voice quality and volume are noted. Palpation defines thyroid size, symmetry, and consistency, as well as the number, size, location, consistency, tenderness, and mobility of nodules; the number, size, location, and mobility of cervical lymph nodes; and the presence of tracheal deviation or substernal extension. A firm, mobile, solitary nodule is most often a colloid nodule or simple cyst but also may represent follicular adenoma; a hard, fixed mass suggests cancer but may represent Hashimoto disease. Central or unilateral adenopathy favors PTC or MTC. Thyromegaly of variable texture and multiple nodules are most common with MNG; substernal extension may produce cervical tracheal deviation or venous engorgement. General medical status should be assessed as for any potential preoperative patient.

Table 2 Benign Etiologies of Euthyroid Nodular Disease		
Disease	Nodularity	Predominant Treatment
Colloid nodule	Solitary or multiple	Observation
Simple cyst	Solitary or multiple	Observation or aspiration if > 4 cm or growing
Follicular adenoma (FA)	Solitary or multiple	Resection (thyroid lobectomy) to exclude malignancy
Multinodular goiter (MNG)	Often with dominant nodule in multinodular gland	Resection for compressive symptoms, dominant nodule > 4 cm, or suspicious dominant nodule
Chronic lymphocytic thyroiditis (Hashimoto disease)	Heterogeneous gland; may have dominant nodule	Resection for compressive symptoms or if suspicious dominant nodule

Table 3 Malignant Etiologies of Euthyroid Nodular Disease	
Disease	Percentage
Papillary thyroid cancer (PTC)	80
Follicular thyroid cancer (FTC)	10
Hürthle cell cancer (HCC)	1
Anaplastic thyroid cancer (ATC)	2
Medullary thyroid cancer (MTC)	5
Lymphoma	1
Metastases	< 1

Table 4 Familial Syndromes of Thyroid Disease

Syndrome	Thyroid Disease	Gene/Tumor Marker
MEN type IIA	Medullary thyroid cancer	<i>ret</i> proto-oncogene/calcitonin
MEN type IIB	Medullary thyroid cancer	<i>ret</i> proto-oncogene/calcitonin
FMTC	Medullary thyroid cancer	<i>ret</i> proto-oncogene/calcitonin
Familial adenomatous polyposis	Papillary thyroid cancer	<i>APC</i>
Carney complex	Well-differentiated thyroid cancer	<i>PRKARIA</i>
Cowden disease (<i>PTEN</i> multiple hamartoma syndrome)	Follicular adenoma/follicular carcinoma	<i>PTEN</i>
Peutz-Jeghers syndrome	Well-differentiated thyroid cancer	<i>STK 11</i> or <i>LKB 1</i>

FMTC = familial medullary thyroid carcinoma; MEN = multiple endocrine neoplasia.

Ultrasonography

Further assessment is accomplished with US, a safe, non-invasive, cost-effective means of imaging thyroid parenchyma and the cervical nodal basins. Patients are categorized as having solitary or multiple nodules, and lesions are subdivided into cystic, solid, or mixed cystic-solid. In a multinodular thyroid, a particularly large or irregular nodule is termed dominant. Benign nodules typically are round, homogeneous, slightly hypoechoic, and easily separable from surrounding tissue. Malignant nodules are more often irregular in shape, heterogeneous, markedly hypoechoic, and poorly demarcated. Tiny, hyperechoic, “comet tail”-shaped lucencies in a nodule favor benignity, whereas fine internal calcifications or hypervascularity suggests malignancy.¹⁸ Thin-walled cysts without internal echoes are overwhelmingly benign; mixed cystic-solid nodules are indeterminate and grouped with solid lesions for further evaluation.

Fine-Needle Aspiration

FNA provides the most accurate, cost-effective assessment of thyroid nodules. Benign lesions comprise 70% of FNA results, whereas roughly 5% of FNA are read as definitively malignant. Most of the remaining lesions are “follicular aspirates,” ranging from hyperplastic nodules to follicular cancer. A benign FNA diagnosis is credible^{19,20} and requires no further intervention other than periodic screening. The sensitivity and specificity of FNA for the diagnosis of malignancy approach 94% and 99%, respectively.²¹ A standardized thyroid FNA reporting system (Bethesda criteria) has recently been advocated.²² There are six general diagnostic categories: nondiagnostic or unsatisfactory, benign, atypia of undetermined significance (AUS) or follicular lesion of undetermined significance (FLUS), suspicious for follicular neoplasm, suspicious for malignancy, and malignant. Risk of malignancy varies by category [see Table 5]. FNA of solid solitary or dominant nodules greater than 1 cm is appropriate in most cases. Solid lesions 5 to 10 mm may warrant FNA if the nodule is hypoechoic and microcalcifications are present, if the history discloses a high risk for cancer, or if they are found on an

Table 5 Bethesda Classification of FNA Cytology and Associated Malignancy Risk

Bethesda FNA Cytology Class	Risk of Malignancy (%)
Nondiagnostic/unsatisfactory	1–4
Benign	0–3
AUS/FLUS	5–15
Suspicious for follicular neoplasm	15–30
Suspicious for malignancy	60–75
Malignant	97–99

AUS = atypia of undetermined significance; FLUS = follicular lesion of undetermined significance; FNA = fine-needle aspiration.

unrelated fluorodeoxyglucose-positron emission tomographic (FDG-PET) scan.^{14,23} When US confirms MNG and compression symptoms are absent, FNA is indicated for the dominant nodule.

Sequencing of Investigations

US typically precedes FNA as US findings may change the FNA target (e.g., an unsuspected suspicious nodule). “Pure” cystic lesions are rare, are overwhelmingly benign, and can be observed without FNA for diagnosis when asymptomatic. When a mixed nodule has a substantial cystic component, US-guided FNA allows fluid aspiration for cytology and FNA of the residual solid component. For solid nodules, US-guided FNA can reduce the rates of nondiagnostic and false negative results when the likelihood of inadequate material or sampling error is high (difficult to palpate, posteriorly located).¹⁴ Operation without FNA is indicated for a solitary or dominant nodule exceeding 4 cm given the substantial chance of malignancy and the possibility of nonrepresentative sampling by FNA (although many clinicians obtain a biopsy for the purpose of operative planning). FNA is also unnecessary when US confirms MNG in a patient with compression symptoms.

MORPHOLOGY-BASED TREATMENT CONSIDERATIONS

Cystic Lesions

Incidentally discovered simple cysts do not require investigation or treatment. Clinically evident cysts are aspirated dry and the fluid sent for cytology. Benign cysts commonly recur and are reaspirated; thyroid lobectomy is indicated after two failed aspirations or for cysts greater than 4 cm. Percutaneous ethanol injection carries a 20% recurrence rate and is an alternative treatment for smaller cysts.¹⁴ Mixed cystic-solid nodules are managed like solid lesions based on cytology and FNA results.

Multinodular Goiter

Most MNG patients are managed medically with serial clinical evaluations (examination, TFT, and US) unless compressive symptoms

or dominant nodules develop. Thyroidectomy is indicated for patients with US findings of MNG and compressive symptoms. Compressive symptoms are typically associated with markedly asymmetrical goiters or those with substernal extension. When examination or US findings are inconsistent with symptomatology, CT or MRI can help exclude other etiologies. These cross-sectional modalities are also useful to delineate the extent of the mediastinal component if present.

Indications for surgery include compressive symptoms, severe or bothersome cosmetic deformity, any dominant nodule greater than 4 cm, or any nodule greater than 1 cm with FNA results that meet the criteria for removal. Total thyroidectomy is preferred over lesser resections to minimize recurrent disease from remnant hypertrophy and is appropriate for these patients when done by surgeons with low complication rates. Nearly all substernal goiters can be safely removed through a generous collar incision, and the remaining few are reached via partial sternotomy. Patients with tracheal deviation or substernal goiters may present endotracheal intubation challenges; airway management is optimized by preoperative dialogue between the surgeon and the anesthesiologist. Frozen section adds little value except when preoperative FNA was nondiagnostic or not performed or when intraoperative findings suggest unexpected malignancy.

Solitary or Dominant Nodule

The management of a solitary nodule is highly dependent on cytologic diagnosis and can be broken down into six categories based on the Bethesda criteria.²²

FNA nondiagnostic About 10 to 15% of aspirates are nondiagnostic, most often attributable to technical error, inadequate sampling, or a substantial cystic component. Less than 5% of these are malignant. Repeat FNA often yields adequate and definitive material²⁴; US guidance may enhance yields. Persistently insufficient results should prompt lobectomy.

FNA benign A benign diagnosis is rendered in nearly 70% of all specimens, and no intervention is required. The risk of malignancy is 0.5 to 3%.²² Surveillance by serial clinical evaluations (examination, TFT, and US) is done annually and then less often for stable nodules. Enlarging lesions (50% or more increased volume) warrant repeat FNA.

FNA AUS/FLUS Atypia or follicular lesion of undetermined significance is a heterogeneous subset of cytologically indeterminate nodules; roughly 5 to 15% prove to be malignant.²² AUS/FLUS is managed like FNA nondiagnostic: repeat FNA and then lobectomy if a definitive diagnosis remains elusive. Molecular markers (e.g., *braf*, *ras*) hold promise for future use in this patient subset; FDG-PET specificity is too low to add clinically relevant value.

FNA suspicious for follicular neoplasm Cancer is present in 15 to 30% of suspicious for follicular neoplasm (SFN),²² but the distinction between benign follicular

adenoma and follicular carcinoma cannot be made by FNA cytology. Assessment for malignancy is based on capsular or vascular invasion, and lobectomy is indicated for tissue diagnosis. Completion thyroidectomy is performed for final diagnoses of follicular cancer or follicular variant of papillary cancer. Some patients opt for total thyroidectomy initially to avoid the need for reoperation; this strategy is reasonable when complication rates are kept low.

FNA suspicious for malignancy A small number of abnormal cells within a sparsely cellular or more benign-looking background characterizes lesions in this category. Malignancy rates are 60 to 75%.²² Thyroid lobectomy is the minimum adequate treatment, and total thyroidectomy is preferable when complication rates are low.

FNA malignant Roughly 5% of cytologic diagnoses are conclusively malignant, and the positive predictive value of FNA for cancer is 97 to 99%.²² Comments about the cell type are usually provided. Total thyroidectomy is the preferred treatment for WDTC and MTC, whereas lobectomy suffices for unilateral metastases from other primary sites. Resections for primary thyroid lymphoma and ATC are tailored to the extent of disease, although resection for ATC is usually aimed at palliation only.

High-Risk Patients

Patients exposed to ionizing radiation, especially in childhood or adolescence, have a lifetime increased risk of PTC. Whereas FNA is credible for assessing their nodules, total thyroidectomy should be considered once nodules develop. Patients who retain irradiated thyroids require extremely close surveillance, so noncompliant individuals are better served by operation. A contralateral nodule developing after a lobectomy for cancer most often warrants completion thyroidectomy. Close surveillance is acceptable for compliant patients when FNA is clearly benign. Large (> 4 cm) solitary or dominant nodules should be resected to allow complete histopathologic examination; lobectomy is the minimum acceptable procedure. When intraoperative findings suggest malignancy (e.g., adherence to strap muscles), total thyroidectomy is appropriate for surgeons with low complication rates. For less experienced surgeons or when findings are benign, lobectomy suffices, and further resection decisions are based on the final pathology. Frozen section cannot exclude malignancy in these cases because of the potential sampling error.

Additional Studies

Additional laboratory tests are seldom indicated preoperatively. When the history raises the potential for MTC, the cytopathologist should be alerted and special cytologic stains performed. Any suspicion of MTC on FNA should trigger exclusion of pheochromocytoma and assessment for primary hyperparathyroidism prior to thyroidectomy (plasma or urine metanephrine assays, serum parathyroid hormone and calcium levels). Additional imaging is warranted for palpable cervical adenopathy in the setting of any thyroid malignancy; the modality is selected based on local expertise. US avoids iodinated contrast administration (which confounds postoperative ¹³¹I scanning or therapy), but accuracy is more operator dependent than for CT or MRI. FNA is appropriate

when other etiologies for adenopathy are present or when documented nodal metastases would change management (e.g., lobectomy only is planned, tertiary care referral). For nodes detected only on preoperative imaging, image-guided FNA is used similarly. **Preoperative laryngoscopy to document vocal cord function is indicated for patients with vocal complaints, audible vocal abnormalities, and prior neck operation or radiotherapy, although some surgeons perform laryngoscopy routinely.** Vocal cord paralysis or other concerns for tracheal or esophageal invasion should be investigated by endoscopy and imaging. Vocal cord paralysis should also trigger preoperative dialogue about airway management with both the patient and the anesthesiologist. **Radionuclide scanning is not useful, and the role of FDG-PET in preoperative staging remains ill-defined.**

Intraoperative observations may lead to revision of the operative plan. Strap muscle adherence, adjacent soft tissue invasion, and extracapsular tumor extension are consistent with malignancy and favor total thyroidectomy. Contralateral disease palpable through the strap muscles warrants at least FNA (through the muscles) and consideration of total thyroidectomy. To lessen the morbidity of reoperation, the contralateral strap muscles should not be elevated unless resection is planned at the same operative session. **Suspicious nodes may be evaluated by FNA or frozen section. Multiple suspicious central nodes or a positive biopsy result merit central lymphadenectomy [see Figure 1, Level VI].** Central neck dissection also should be considered by surgeons with low complication rates for T3 or T4 WDTC tumors

even though nodal disease is absent. **Proven lateral nodal disease is best treated by level II–IV en bloc functional resection when appropriate surgical expertise is available [see Figure 1].**

DISEASE-SPECIFIC TREATMENT CONSIDERATIONS

Papillary Thyroid Cancer

PTC is the most common thyroid cancer and carries an excellent prognosis when treated appropriately (> 90% 10-year survival overall). Poor prognostic factors include age less than 20 or more than 60 years, tumor greater than 4 cm, extrathyroidal extension, and the presence of distant metastases.^{25,26} Lymphatic spread worsens the prognosis and increases local recurrence risk for patients over 45 years and those with clinically apparent nodal involvement.¹⁴ The tall cell, columnar, diffuse sclerosing, trabecular, and insular variants are more aggressive but uncommon. The follicular variant is more common but behaves more like classical PTC. One quarter of PTCs are multicentric, and lymph nodes are involved at the initial presentation in about one third.²⁷ Distant metastases, usually pulmonary, are present initially in 5% of cases. PTC rates are sharply increased by ionizing radiation, with a lag time of 15 to 25 years. The high long-term survival rates of PTC patients and paucity of large randomized controlled trials have contributed to inconsistent treatment guidelines and to multiple prognostic scoring systems [see Table 6]. Staging should follow the TNM classification [see Table 7]. Most scoring systems correlate with recurrent disease, whereas the TNM system links best to mortality. Recent consensus evaluation and treatment recommendations from the American Thyroid Association are achieving widespread recognition.¹⁴

Total thyroidectomy should be performed for most PTCs exceeding 1 cm²⁸; this procedure addresses multicentricity, maximizes the therapeutic impact of postoperative RAI, and facilitates surveillance for recurrences. Lobectomy suffices for small, intrathyroidal PTC discovered incidentally in glands resected for other diagnoses when radiation exposure, nodal disease, and poor prognostic variants are absent. Central neck dissection is added based on FNA or operative findings suggesting lymphatic spread [see Figure 1, Level VI]. Judicious addition of prophylactic dissection by surgeons with low complication rates is reasonable, particularly for patients over 45 years, larger tumors (T3–T4), and more aggressive histologies.^{14,27} The favorable natural history of PTC and the morbidity of lateral cervical lymphadenectomy suggest that this procedure be added only for pathologically proven lateral nodal disease. An aggressive operative approach should be considered in good operative candidates with PTC invading the trachea or esophagus. A functioning recurrent laryngeal nerve (normal vocal cord function) should seldom, if ever, be sacrificed.

Postoperative administration of RAI for thyroid remnant ablation may also have an adjuvant therapeutic effect on residual microscopic disease in the central neck. RAI ablation is indicated when nodal or distant metastases are known to be present and for T3–T4 tumors.¹⁴ Ablation may also reduce recurrence rates for N1 disease or T2 tumors. Lifelong levothyroxine is given postoperatively at doses sufficient to suppress TSH secretion without causing overt hyperthyroidism. Dose reduction may be required if the osteoporosis risk

Figure 1 Cervical lymph nodes can be classified into six levels (*inset*) on the basis of their location in the neck.

Table 6 Elements of Common Prognostic Schemes for Well-Differentiated Thyroid Cancer

Prognostic Scheme	Patient Characteristics		Tumor Characteristics						Operative Factors
	Age	Gender	Size	Histologic Grade	Histologic Subtype	Extrathyroidal Extension	Nodal Metastasis	Distant Metastasis	Completeness of Resection
AGES	+	–	+	+	*	+	–	+	–
AMES	+	+	+	–	+	+	–	+	–
MACIS	+	–	+	–	*	+	–	+	+
MSKCC	+	–	+	+	+	+	+	+	–

+ = variable used in defining risk group; – = variable not used; * = only for papillary thyroid carcinoma; AGES = patient age, tumor grade, extent, and tumor size; AMES = patient age, presence of distant metastases, extent, and tumor size; MACIS = metastatic lesions, patient age, completeness of resection, invasion, and size of tumor; MSKCC = Memorial Sloan-Kettering Cancer Center scheme.

Table 7 Staging of Differentiated Thyroid Cancer

Tumor Type	Stage	Patient Age (yr)	Tumor	Node	Metastasis
PTC/FTC	I	< 45	Any T	Any N	M0
	I	45 or older	T1	N0	M0
	II	< 45	Any T	Any N	M1
	II	45 or older	T2	N0	M0
	III	45 or older	T3	N0	M0
	III	45 or older	T1–3	N1a	M0
	IVA	45 or older	T4a	N0–1a	M0
	IVB	45 or older	T4b	Any N	M0
	IVC	45 or older	Any T	Any N	M1

FTC = follicular thyroid cancer; PTC = papillary thyroid cancer.

is high or atrial fibrillation develops. Postoperative surveillance can include RAI whole body scan, serum Tg levels, and cervical US; test combinations and frequencies are individualized based on tumor staging, estimated recurrence risks, and patient compliance. Anti-Tg antibodies should be measured simultaneously with each Tg assay.

Follicular Thyroid Cancer

FTC comprises 10 to 15% of thyroid malignancies. In contrast to PTC, FTC is typically solitary, and metastasis is more often hematogenous than lymphatic, favoring lung and bone. Poor prognostic factors include age over 50 years and tumors over 3.5 cm. An FTC with a limited area of microscopic capsular invasion and no vascular invasion is termed “minimally invasive” and carries no excess mortality when treated by thyroid lobectomy. Total thyroidectomy is indicated for more extensive capsular invasion or for vascular invasion. Central [see Figure 1, Level VI] or lateral lymphadenectomy [see Figure 1, Level II–IV] is performed for clinically evident or palpable nodal disease. Staging follows the TNM classification. RAI ablation is indicated for all FTCs except minimally invasive lesions. Levothyroxine suppression is given, and surveillance is performed as for PTC. Stage for stage, FTC and PTC have equivalent prognoses.

Oncocytic (Hürthle Cell) Carcinoma

Hürthle cell carcinomas (HCCs) comprise less than 5% of WDTCs and are a subset of follicular neoplasms. They

contain at least 75% oncocytes and demonstrate capsular or vascular invasion. Oncocytic cancers are considered more aggressive than classical FTC because extrathyroidal extension and metastases (nodal and distant) are more common and RAI uptake is often minimal.^{15,29} Total thyroidectomy is indicated for nearly all HCCs, although this is often done in a two-stage fashion because FNA cannot provide a definitive diagnosis. Central or lateral lymphadenectomy is performed when nodes are clinically positive. Staging should follow the TNM classification. RAI ablation is indicated for all HCCs, and levothyroxine suppression is given as for FTC. Surveillance includes US and Tg; FDG-PET may be useful when Tg is elevated and a radioiodine whole body scan is negative.

Anaplastic Thyroid Cancer

ATC is rare in the United States, representing less than 2% of thyroid malignancies.^{29,30} The median survival for patients with ATC is approximately 6 months.^{15,30} ATC is suspected when older patients present with rapidly progressive, bulky, fixed tumors. Diagnosis may require core-needle or incisional biopsy when FNA is inadequate. The vast majority of tumors are unresectable at diagnosis because of locoregional spread. Over 40% of patients have extensive nodal involvement, and nearly 50% present with distant metastases (lung, bone, brain, adrenal).³⁰ Surgery has little utility other than for establishing an airway for palliation. External beam radiotherapy plus chemotherapy may transiently shrink the tumor;

palliative debulking is occasionally feasible for the few patients with significant and sustained responses.

Medullary Thyroid Carcinoma

Unlike WDTC, MTC is a neuroendocrine tumor that arises from the calcitonin-secreting parafollicular cells. MTC constitutes about 5% of thyroid cancers; most (75%) cases are sporadic, whereas the remainder are hereditary. Sporadic disease presents as a solitary nodule, often with palpable adenopathy. Cytologic features are characteristic and confirmed by immunostaining for calcitonin. Distant metastases to lung, liver, and bone are frequent. Staging follows the TNM classification [see Table 8]. Preoperative staging includes neck, chest, and abdominal CT or MRI for all but those with small primary tumors and no adenopathy. Liver and lung lesions are often multiple but sometimes small enough to escape detection via CT. A baseline calcitonin should be measured preoperatively. **Testing to exclude pheochromocytoma also is essential because the patient may represent the index case of an unsuspected kindred with MEN. If present, pheochromocytoma must be resected prior to thyroidectomy for MTC.** Overall survival in MTC is considerably lower when compared with WDTC. Poor prognostic features include large tumor size, high preoperative calcitonin, advanced age, and mediastinal adenopathy.²⁸ Surgery is the only effective treatment modality and should consist of total thyroidectomy plus central neck dissection [see Figure 1, Level 6] and ipsilateral modified radical neck dissection [see Figure 1, Levels I–V]. Contralateral lymphadenectomy is added when bilateral thyroid masses or clinically positive nodes are identified. Extrathyroidal or extranodal tumor extension worsens the prognosis. Calcitonin is followed serially as a tumor marker postoperatively. A subset of patients with persistent or recurrent hypercalcitonemia follow a prolonged course, and reoperation may be indicated when tumor masses are detected by imaging and confirmed by FNA. Aggressive cervical reoperation for persistent hypercalcitonemia alone is controversial. Symptomatic hypercalcitonemia is unusual. RAI has no therapeutic role for MTC.

MTC occurs as a component of three familial syndromes: MEN type IIA, MEN type IIB, and familial medullary

thyroid carcinoma (FMTC). MTC associated with MEN type IIB is the most aggressive, followed by MEN type IIA and then FMTC. Hereditary lesions usually are bilateral and are associated with a precursor lesion termed C-cell hyperplasia. MEN type IIA accounts for two thirds of hereditary MTCs. *Ret* proto-oncogene testing is recommended before age 6 within known kindreds. Prophylactic total thyroidectomy and central neck dissection are performed when a *ret* mutation is confirmed, after excluding pheochromocytoma.^{31,32} MTC has an earlier age at onset in MEN type IIB, and genetic screening is conducted shortly after birth. Positive *ret* testing is followed by total thyroidectomy and central neck dissection in the first year of life.³¹ FMTC is defined by the presence of four or more MTC cases within a family in the absence of associated endocrinopathy. The age at onset of FMTC is delayed compared with that of MEN type II, but FMTC survival is optimized by childhood genetic screening and operation (total thyroidectomy and central neck dissection).

Primary Thyroid Lymphoma

Primary thyroid lymphoma (PTL) accounts for approximately 1% of thyroid malignancies and 1% of extranodal lymphomas.^{27,28} The risk of PTL is increased by Hashimoto thyroiditis. FNA is diagnostic in most cases (80%); core-needle or incisional biopsy may be required for diagnosis or for tumor markers. About 75% of PTL are diffuse large B cell lesions and 25% are mucosa-associated lymphoid tissue (MALT) lymphomas, with MALT lesions carrying a better prognosis.¹⁶ Poor prognostic features include size greater than 10 cm, advanced stage, compressive symptoms, mediastinal involvement, and rapid tumor growth. Constitutional symptoms are rare. PTLs are chemo- and radiosensitive, so multiagent chemotherapy is usually combined with external-beam radiation as definitive treatment. Surgery alone may be appropriate for early-stage MALT tumors.^{16,30} If PTL is diagnosed intraoperatively, total thyroidectomy is appropriate.

Metastases

Metastases to the thyroid are rare. Renal cell and breast tumors are common tumors of origin. FNA will suggest metastatic tumor, although perhaps not identify a specific tumor of origin. When the thyroid is the sole site of metastatic disease, thyroidectomy (lobe versus total) may be curative. Palliative resection is seldom, if ever, appropriate. Preoperative evaluation is tailored to the tumor of origin.

Thyroidectomy: Technique, Tips, and Troubleshooting

OPERATIVE TECHNIQUE

Proper Positioning

The first step to a safe thyroidectomy is positioning the patient to optimize operative exposure. A shoulder roll or a sandbag placed between the scapulas allows the neck to be extended and shifted anteriorly. Proper positioning is particularly important in facilitating access to substernal goiters through the cervical approach. Neck extension must be gentle in all patients and should be limited in patients with known cervical disk disease, rheumatoid arthritis, or osteoporosis. The occiput should be stabilized by support with a foam

Table 8 Staging of Medullary and Anaplastic Cancer

Tumor Type	Stage	Tumor	Node	Metastasis
MTC	I	T1	N1	M0
	II	T2–3	N0	M0
	III	T1–3	N1a	M0
	IVA	T4a	N0–1a	M0
	IVB	T1–4a	N1b	M0
	IVC	T4b	Any N	M0

MTC = medullary thyroid cancer.

pillow. Neck hyperextension or poor occipital support can result in significant postoperative muscle spasm and associated headache.

General Technical Principles

The thyroidectomy incision is located in a cosmetically sensitive area, but exposure should not be compromised by an inadequate incision. A larger operative field is generally needed for resections for Graves disease and toxic multinodular goiters, for large nontoxic multinodular goiters producing compression symptoms (particularly those with substernal components), when preoperative evaluation suggests extrathyroidal extension of tumor, and when there is a high likelihood of performing a lymphadenectomy.

Operative complications are best avoided by unhurried dissection in a bloodless field.^{33,34} If encountered, bleeding can and should be controlled first by pressure so that the relationship of the source vessel to the recurrent laryngeal nerve can be clarified. Early identification of the nerve facilitates safe control of vessels. Suture ligatures should be considered for controlling vessel ends that are likely to retract away from the operative field (e.g., cephalad end of the superior thyroid artery at the superior pole, mediastinal end of a thyroidea ima artery). Operating telescopes (2.5 to 3.5 power magnification) are a useful adjunct during delicate dissection around the recurrent nerve and vascular branches supplying parathyroid glands.

When bilateral resection is planned, dissection should nearly always be done first on the side of the suspected tumor or larger goiter. Should a problem be encountered (e.g., parathyroid involvement by tumor or recurrent nerve operative injury), the operative plan can be revised to a subtotal resection on the contralateral side to enhance protection of the parathyroid glands and recurrent nerve on that side. Rarely, when tumors are known or suspected preoperatively to be very extensive, beginning on the “easy” (less abnormal) side may facilitate identification of and access to the trachea and esophagus.

Step 1: Skin Incision and Subplatysmal Flaps

A collar incision paralleling the normal cervical skin lines offers extensile exposure. Typically, the incision is sited about 1 cm caudad to the cricoid cartilage and extends between the sternocleidomastoid muscles [see Figure 2]. Shifting the incision cephalad should be considered when the superior poles are likely to extend significantly upward (e.g., Graves disease) or caudad when a substernal goiter is present. After dividing the platysma, subplatysmal flaps are raised widely in all directions in this bloodless plane, avoiding the anterior jugular veins that may be particularly prominent in patients with Graves disease or substernal goiters.

Tips and troubleshooting Developing the superior flap to 1 to 2 cm above the thyroid cartilage notch will facilitate later access to the superior poles and the pyramidal lobe. Taking the inferior flap until the flat surface of the manubrium is palpable will aid exposure of substernal goiters. A retractor with attachable side-arm blades (e.g., the Mahorner-Hamburger-Brennan) is particularly useful for operations on larger glands but requires a slightly longer skin incision for atraumatic placement into the neck.

Figure 2 The initial incision in a thyroidectomy is made 1 cm below the cricoid cartilage and follows normal skin lines. A sterile marking pen is used to mark the midline of the neck, the level of the incision, and the lateral borders of the incision. A 2-0 silk tie is pressed against the neck to mark the incision site itself.

Step 2: Mobilization of Strap Muscles

The thyroid gland is exposed by dividing the investing and pretracheal layers of the cervical fascia in the midline. The sternohyoid and sternothyroid muscles can then be elevated as a single unit on each side off the thyroid lobe in what is usually a bloodless plane [see Figure 3]. The dissection is carried laterally until the lateral border of the sternothyroid muscle is easily seen. Partial or complete division of the sternothyroid muscle at its insertion into the thyroid cartilage can significantly improve exposure of the superior pole while avoiding denervation of the muscle. Routine division of both strap muscles is unnecessary in most cases. Once the strap muscle unit is elevated fully, side-arm blades can be inserted and fixed to the self-retracting retractor for lateral retraction of the strap muscles.

In patients operated on to exclude or to treat malignancy, a deliberate pause prior to further dissection is appropriate after the strap muscle unit is fully elevated from the thyroid lobe. The size, location, color, and consistency of the solitary or dominant nodule should be noted, along with the integrity of the overlying thyroid capsule and the presence of fibrosis in or adherence of adjacent soft tissues to the lobe. The characteristics of visible central neck lymph nodes should be assessed.

Tips and troubleshooting The midline fascia should be opened down to the inferior aspect of the sternal notch, where the interclavicular ligament can be palpated, facilitating later mobilization of substernal goiter, identification of inferior parathyroid glands, and central lymphadenectomy.

Tissue attachments or vessels crossing the plane between the thyroid and the midline strap muscles are concerning for malignancy, and any densely adherent portion of strap muscle should be sacrificed and left attached to the underlying thyroid for en bloc resection. This maneuver will also aid the pathologist later in determining extrathyroidal extension of tumor, a finding that is an important predictor of recurrence. Tissue reaction to a preoperative FNA biopsy can simulate tumor adherence. Benign central lymph nodes should be

Figure 3 To expose the thyroid, a midline incision is made through the superficial layer of deep cervical fascia between the strap muscles. The incision is begun at the suprasternal notch and extended to the thyroid cartilage.

small, firm but not hard, and mobile and have well-defined capsules; nodes appearing otherwise should be regarded as suspicious, and intraoperative FNA should be considered. Benign lymphadenopathy is most often associated with Graves disease and Hashimoto thyroiditis.

Step 3: Initial Mobilization of the Thyroid Lobe and Superior Parathyroid Gland Identification

SCORE A 2-0 suture is placed deeply through the thyroid lobe for retraction to facilitate exposure. The stitch should not traverse a thyroid nodule as it is more likely to pull loose and may create artifacts that confound later histopathologic interpretation. The lobe is retracted medially while the filmy soft tissue lateral to the lobe is divided close to the gland. Dissection parallel to the usual course of the recurrent laryngeal nerve is safest. The addition of inferior traction facilitates carrying the dissection up to the superior pole. Vessels are controlled and divided near or on the surface of the lobe whenever feasible, limiting risk to the nerve and minimizing the chance of parathyroid devascularization. The superior thyroid artery is best managed by dividing it at the branch level, controlling the individual branches low on the thyroid gland, which minimizes the risk of injury to the external branch of the superior laryngeal nerve [see Figure 4].

Tips and troubleshooting A small sponge applied to the gland surface further facilitates lobar retraction and lessens trauma to the thyroid surface, particularly when the gland is hypervascular (e.g., Graves disease). Palpation of the inferior cornu of the hyoid bone is advisable as the lobe is retracted medially and caudally as a guide to the location of the recurrent nerve, which enters the cricothyroid muscle in close proximity to the cornu. As the lobe is rotated medially and the superior pole branches are divided, the superior parathyroid gland usually is easily seen and should be gently freed from the perithyroidal soft tissue [see Figure 5]. The parathyroid with its adjacent soft tissue and fat is gently swept away from the thyroid.

Step 4: Recurrent Laryngeal Nerve Identification

SCORE It is usually safest to identify the recurrent laryngeal nerve low in the neck and then to follow it to where it enters the

Figure 4 The superior pole vessels should be individually identified and ligated low on the thyroid gland to minimize the chances of injury to the external branch of the superior laryngeal nerve.

cricothyroid muscle through the Berry ligament [see Figure 6]. With the thyroid lobe retracted medially and anteriorly, the nerve is put on stretch and can be palpated as a taut, linear structure (“guitar string”) slightly inferior to the inferior thyroid artery. The filmy soft tissue overlying the nerve can be lifted anteriorly away from the nerve and divided under direct vision, allowing the nerve to be followed to its cricothyroid entry. Sharp, fine-bladed scissors (e.g., tenotomy, Jameson) and fine-tipped hemostats (“mosquito”) are essential instruments for this step. Having looped around the right subclavian artery, the right recurrent nerve follows a more oblique lateral-to-medial course than the left nerve, which follows a straight vertical course somewhat more deeply in the tracheoesophageal groove, having looped around the ductus arteriosus in the mediastinum.

Figure 5 The upper parathyroid glands are usually situated on either side of the thyroid at the level where the recurrent laryngeal nerve enters the cricothyroid muscle. The lower parathyroid glands are usually anterior to the recurrent laryngeal nerve and inferior to where the inferior thyroid artery crosses this nerve.

Figure 6 The recurrent laryngeal nerve enters the cricothyroid muscle at the level of the cricoid cartilage, first passing through the Berry ligament.

Tips and troubleshooting In about 0.5% of persons, the right recurrent laryngeal nerve is, in fact, “nonrecurrent,” arising as a direct branch from the vagus in the midneck and coursing toward the thyroid from either laterally or superiorly.¹ Rarely, both a recurrent and a nonrecurrent nerve are present on the right. Branching of the nerve is common on both sides, and all branches must be preserved because all of the motor fibers of the recurrent laryngeal nerve are usually in the most medial branch. Initial identification of the nerve near the level of the inferior thyroid pole rather than

superiorly will usually allow identification of any nerve branches. Some surgeons find intraoperative nerve monitoring to be helpful, but its use is not uniform among endocrine surgeons.³⁵

Step 5: Thyroid Mobilization and Identification of Inferior Parathyroid Glands

Once the course of the recurrent laryngeal nerve has been identified, the lobe can be further rotated medially along its length and around the inferior pole, again controlling vessels

close to the lobar surface. During this dissection, the inferior parathyroid gland is typically seen. Located in a plane anterior to the recurrent nerve, the parathyroid gland often appears attached to the capsule of the inferolateral thyroid pole. The attachment is filmy and easily separated, but care must be taken to avoid injuring the small vessels to the parathyroid.

Tips and troubleshooting Parathyroid glands should be swept from the thyroid gland on as broad a vascular pedicle as possible to prevent devascularization. If the pedicle is injured or if the parathyroid changes from its normal dark mustard color to a dusky purple, a tiny piece of the gland should be sent for frozen section to confirm its identity as parathyroid. Once confirmed, the gland is resected and put on sterile iced slush for autotransplantation into the sternocleidomastoid muscle just prior to closure.

In patients who have invasive tumors or who require reoperation, extensive scarring is often present. It may be preferable to identify the recurrent laryngeal nerve from a superior and medial approach by dividing the isthmus and the superior thyroid vessels. Careful medial to lateral rotation of the thyroid lobe from the trachea allows visualization of the nerve at its most consistent location (i.e., at its entrance into the larynx immediately posterior to the cricothyroid muscle). Alternatively, the nerve can be approached from laterally by identifying the lateral border of the sternothyroid muscle at the level of the inferior thyroid pole and working medially toward the inferior thyroid artery. The approach is modified to maximize dissection through the least scarred plane.

Step 6: Mobilization of the Pyramidal Lobe

A pyramidal lobe is found in about 80% of patients. This embryologic remnant usually arises from the left thyroid lobe near the midline and extends for a variable distance cranially. Inferior traction on the left lobe will bring most if not all of the pyramidal lobe into the operative field. The pyramidal lobe is dissected free medially and laterally from adjacent soft tissue and is transected at its cephalad termination. It is left attached to the main thyroid mass caudally and resected en bloc. As the pyramidal lobe is mobilized, one or more central neck nodes may be encountered overlying the cricothyroid membrane (so-called Delphian nodes) [see Figure 7].

Tips and troubleshooting The pyramidal lobe may extend to the base of the tongue as a thyroglossal duct remnant, but it is often just a fibrotic strand, particularly superior to the hyoid bone. Complete resection of the pyramidal lobe up to the tongue and removal of the middle third of the hyoid bone are important components of the Sistrunk operation for thyroglossal duct cyst. Resection of the pyramidal lobe within the usual thyroidectomy operative field without hyoid excision is sufficient during thyroid resection for other diseases.

Step 7: Completing the Thyroid Resection

Once the lobe has been mobilized superiorly, inferiorly, and laterally, it must be freed from its attachments to the trachea. As the lobe is rolled from lateral to medial, the most challenging part of the dissection involves the thyrotracheal ligament (Berry ligament), connecting the posterior aspect of the lobe to the trachea just caudal to the cricoid cartilage [see Figure 6]. A small branch of the inferior thyroid artery traverses the ligament, as do one or more thyroid veins; controlling bleeding from these vessels risks recurrent nerve injury as the nerve passes through or under the ligament. Should bleeding occur, it should be controlled by applying pressure with a gauze pad, avoiding clamps and ligatures until the course of the nerve through the ligament has been clearly delineated. Irrigating the field to limit blood staining of tissues is helpful. In some patients, a lateral projection of the thyroid (the tubercle of Zuckerkandl) overlies the nerve and ligament. Once the thyrotracheal ligament has been divided, the remaining thyroid attachments to the trachea can be divided through what is usually an avascular plane on the tracheal surface.

Division of the isthmus should be done between clamps and the ends suture ligated. When lobectomy is performed, the point of division should be at the junction of the isthmus with the contralateral lobe that will remain in situ. Division of the isthmus may be done earlier in the dissection when doing so will facilitate thyroid retraction or mobilization.

Tips and troubleshooting If bilateral resection will be performed, the isthmus may be left intact until the contralateral lobe is dissected free and the entire gland delivered as a

Figure 7 Delphian lymph nodes may be found just cephalad to the isthmus over the cricothyroid membrane.

single specimen The thyroid lobe should be carefully examined after removal. If a parathyroid gland is identified with the specimen, a frozen section biopsy is sent for confirmation and the gland is autotransplanted back into the neck unless the parathyroid appears to be involved by thyroid tumor extension (see above). The resected thyroid should be oriented for the pathologist; marking sutures or clips are helpful for this purpose.

Step 8: Closure

The best strategy to avoid a postoperative neck hematoma is taking time to ensure meticulous hemostasis prior to closure. Thorough irrigation of the field followed by precise identification and control of bleeders should be repeated as necessary until the field is hemostatic and dry throughout. The recurrent nerve should always be reidentified prior to placement of clamps or ligatures. The sternothyroid and sternohyoid muscles are reapproximated as separate layers in the midline. The platysma is closed as a separate layer once the subplatysmal flaps have been released from the self-retaining retractor and verified to be hemostatic. The skin can be closed in several ways, including subcuticular suture, butterfly clips, or tissue adhesive; the key factor in cosmesis is gentle tissue handling, not the closure method.

Smooth emergence from anesthesia with avoidance of coughing and retching can reduce the chance of high pressures being transmitted to the neck veins, and administration of an antiemetic during closure can be helpful, along with spraying the oral cavity with a topical local anesthetic. Endotracheal extubation with the patient still in a relatively “deep” plane of anesthesia is also helpful if not otherwise contraindicated. If postoperative laryngoscopy is contemplated, insertion of a nasal pack containing cocaine or another local anesthetic and decongestant during wound closure will facilitate early flexible fiberoptic endoscopy in the operating room or postanesthesia care unit.

Tips and troubleshooting It is not necessary to reattach a divided sternothyroid muscle to its thyroid cartilage insertion. However, the distal sternothyroid segment should be stretched to full length during closure to allow accurate approximation to the contralateral sternothyroid muscle. When both sternothyroid muscles have been divided superiorly, they can be anchored by including bites of both sternohyoid muscles at the cephalad end of the sternothyroid layer closure.

Drainage of the thyroid bed is no substitute for adequate hemostasis. A drain does not prevent wound hematoma, nor does it provide “early warning” of significant wound hemorrhage. A suction drain placed beneath the midline strap muscle closure may be useful when there is a large dead space in the resected thyroid bed (e.g., after excision of very large goiters). The drain is generally removed on postoperative day 1.

When a subcuticular closure is performed, a patient-friendly wound dressing can be created using a clothlike strip (e.g., roller gauze, Cover Strip II) placed directly over the incision and painted with collodion to render it waterproof. The patient is allowed to shower or wash over the wound beginning on the first postoperative day. The dressing separates from the skin at 7 to 10 days and is easily removed by the patient at that time.

EARLY POSTOPERATIVE CARE

Unilateral Resection (Lobectomy)

Thyroid lobectomy is often accomplished successfully on an outpatient or ambulatory basis, particularly when regional anesthesia is used. Patients with multiple comorbidities or those living in remote areas may be candidates for overnight observation, along with those failing to meet ambulatory surgical unit discharge criteria. The patient is maintained in a gentle head-up position (10° to 20°) for the first 24 hours when nonambulatory to enhance venous drainage and minimize edema formation. After regaining consciousness at a level sufficient to protect the airway, the patient is allowed liquid intake and can be advanced to a regular diet by the following morning. Liberal use of antiemetics during the early postoperative period will minimize retching and emesis. Initial patient-controlled analgesia should be transitioned to oral analgesics as soon as smooth swallowing is observed. Unless there has been neck surgery previously, there is no risk of clinically important hypocalcemia after thyroid lobectomy. It is unnecessary to measure serum calcium levels or to prescribe prophylactic calcium supplementation. The quality of the voice and the adequacy of the airway should be assessed in the postanesthesia care unit and prior to discharge to home. If there is any concern about the integrity of recurrent laryngeal nerve function, flexible fiberoptic laryngoscopy should be performed. Finally, if there is any question of a developing neck hematoma, the patient should be kept hospitalized for airway monitoring. A tray with sufficient instruments to reopen the neck incision urgently is kept at the bedside (e.g., tracheostomy tray).

Bilateral Resection

Patients undergoing bilateral thyroid resections are typically observed overnight or admitted for a brief inpatient stay. Patients undergoing removal of extensive tumors, tracheal or esophageal resections, or lymphadenectomies have longer lengths of stay. Positioning, antiemetics, diet, and patient-controlled analgesia are given as for lobectomy. Severe sore throat may be improved by topical anesthetic spray or solution. **Voice quality and airway adequacy should be assessed in the postanesthesia care unit and periodically thereafter; any concern about the integrity of recurrent laryngeal nerve function should be evaluated promptly with flexible fiberoptic laryngoscopy.** Patients with known coagulation abnormalities or evidence of neck hematoma merit close monitoring in a special care unit for 24 to 48 hours. A tray with sufficient instruments to reopen the neck incision urgently is kept at the bedside (e.g., tracheostomy tray).

Patients undergoing bilateral resections (or completion thyroidectomy after prior lobectomy) are at risk for transient or permanent hypoparathyroidism; the risk is increased with malignancy and by lymphadenectomy. **Strategies for detecting and treating hypocalcemia vary among surgeons.³⁶ Total calcium is more often available and less expensive compared with ionized calcium. In some series, postoperative parathyroid hormone levels are early predictors of hypocalcemia, but parathyroid hormone may not always be available. In the absence of symptoms (perioral tingling, digital paresthesias), there is little reason to measure serum calcium until the morning of postoperative day 1. An exception might be when multiple parathyroid glands have been autotransplanted or when parathyroid tissue is excised deliberately en bloc with**

SCORE

SCORE

SCORE

tumor. A simultaneous albumin level allows correction of the total calcium level for hemodilution by perioperative fluids; otherwise, ionized calcium alone is the optimal single measurement. An elevated serum phosphate level (> 4.5 mg/dL) denotes an increased risk of parathyroid hypofunction. Magnesium assay is performed when patients are symptomatic because hypomagnesemia can mimic or worsen hypocalcemia. An abnormal calcium value (unexplained by hemodilution) when symptoms are absent merits reassessment in 6 to 8 hours and again on postoperative day 2. Symptomatic patients and those with total calcium values less than 7.5 mg/dL warrant treatment. When symptoms are minimal, oral calcium suffices; calcium citrate is the best absorbed of the calcium salts. Severe symptoms (e.g., dark vision, feelings of doom) or neuromuscular findings (e.g., Trousseau sign or claw hand) merit intravenous calcium; calcium gluconate is the least problematic if extravasated. Calcium is remeasured if treatment is required and reaches a steady state 5 to 6 hours after oral dosing. Vitamin D supplementation is seldom necessary but is useful for patients who have required intravenous calcium or who are marginally controlled by 3 to 4 g calcium citrate total daily doses. 1,25-Dihydroxycholecalciferol is the maximally effective vitamin D agent and is given in one to two doses daily (0.5 to 1.0 μ g total daily dose). Some surgeons use a strategy of routine postoperative oral calcium (1.5 to 3 g daily, with or without vitamin D) for all patients after bilateral resections to facilitate early discharge to home. Serum calcium is measured at the first postoperative visit and weaned as tolerated thereafter.

POSTOPERATIVE THYROID HORMONE MANAGEMENT

The half-life of T_4 is long enough that thyroid hormone replacement can be withheld safely until the final surgical pathology results are available. Awaiting the final diagnosis allows efficient, individualized treatment. Previously euthyroid patients seldom become hypothyroid after lobectomy alone. TFT measurement by the patient's primary care physician at 6 months (sooner if hypothyroid symptoms develop) will detect most patients who need T_4 supplementation. Older patients and those with Hashimoto disease are at greatest risk.

Patients will require T_4 therapy after bilateral resections. For patients with benign disease, levothyroxine can be started as soon as the pathology results are known. For patients with cancer, a decision for or against RAI will guide next steps.

When RAI will be given, efficient preparation with minimal hypothyroid symptoms is accomplished by giving low-dose T_3 (50 μ g b.i.d.) for 3 weeks. One week thereafter, most patients will have a TSH level suitable for RAI administration. Alternatively, patients may be given no thyroid hormone for the 4 weeks prior to RAI administration, but this approach more often results in bothersome symptoms. Patients can also reach appropriately high TSH levels by administration of recombinant human TSH for a brief period prior to giving RAI; this option, however, is very expensive, and the efficacy of RAI using this approach is not conclusively known. A baseline Tg level is most sensitive for the detection of residual thyroid tissue and/or residual WDTC when measured while the patient is thyroprival (TSH is elevated). Anti-Tg antibody assay should be measured along with each Tg level; Tg is unreliable when antibodies are present.

Regardless of the RAI preparation approach chosen, T_4 is started after RAI treatment and/or whole body scan.

Replacement, achieving a TSH level within the normal range, is the treatment goal for patients with benign diagnoses. For patients with WDTC, suppression such that TSH is undetectable is the therapeutic target. Lower T_4 doses (less suppression) should be considered for older patients, those with cardiac disease, when osteoporosis risks are increased, or when clinically important hyperthyroid symptoms develop on full suppression. Some clinicians favor full suppression for the first few years postoperatively and then T_4 dose reduction to replacement levels if there is no evidence of recurrent WDTC. A steady-state TSH level is reached at 4 to 6 weeks after starting T_4 or after a dose adjustment.

Patients with MTC, ATC, or lymphoma are started on replacement doses of T_4 postoperatively because there is no proven benefit to TSH suppression in these diseases.

COMPLICATIONS

Thyroidectomy is well tolerated by most patients. General postoperative complications such as atelectasis and deep vein thrombosis or pulmonary embolism are possible but less common than after intracavitary operations. Thyroidectomy is a clean operation, and wound infection should be rare. If wound infection occurs, however, it is potentially quite serious. Infection-related soft tissue edema can lead to airway compromise, and local infection can progress to mediastinitis since the soft tissues of the thoracic inlet are usually opened during thyroidectomy. Thyroidectomy should be postponed if a patient arrives for operation with a recent history or current symptoms of acute pharyngitis.

Complications specific to thyroidectomy include neck hematoma or seroma, recurrent or external laryngeal nerve injury, and transient or permanent hypoparathyroidism. Postoperative bleeding into the neck can produce life-threatening airway compromise, and any postoperative respiratory distress should raise concern for neck hematoma. Urgent bedside decompression by reopening the wound down through the strap muscles is lifesaving when symptoms are sudden and severe. The patient is then returned to the operating room for wound exploration and reclosure under anesthesia. Neck hematoma development with few or no symptoms merits intensive care unit observation for at least 24 hours. Most bleeding occurs within 4 hours of operation, and virtually all occurs within 24 hours. Neck seroma is particularly likely after resection of very large goiters because of the residual dead space, and subplatysmal fluid is ballotable early postoperatively. In the absence of airway symptoms or persistent dysphagia, reassurance of the patient is the only intervention necessary. Percutaneous aspiration is performed for airway or swallowing symptoms or when preferred by the patient for cosmetic or comfort reasons.

Symptoms or signs of airway compromise not attributable to neck hematoma may indicate injury to the recurrent laryngeal nerves. Prompt performance of flexible fiberoptic laryngoscopy allows assessment of vocal cord position and function along with evaluation for other etiologies of respiratory distress (laryngeal edema, laryngospasm). Diagnostic laryngoscopy should not delay securing the airway of a patient with true stridor. Laryngoscopy may, however, be a useful adjunct to rapid, safe reintubation. Paretic or paralyzed vocal cords warrant reintubation. Symptomatic patients who are maintaining their oxygenation without tachypnea may benefit from inhaling a helium-oxygen admixture. The clinical

response is rapid, and the admixture should be continued for several hours before attempting weaning to supplemental oxygen alone.

The reintubated patient should be kept in a head-up position for 36 to 48 hours. A parenteral dexamethasone bolus may be useful at the time of reintubation and carries little risk. Once the patient has mobilized his perioperative fluids and has minimal neck edema (usually by 48 hours postoperatively), airway reassessment can be undertaken. The patient who can vocalize and move air through the larynx with the endotracheal tube in place but with the cuff deflated is likely to tolerate extubation. Flexible laryngoscopy should be done immediately postextubation to document vocal cord function and adequate airway lumen. Close observation for an additional 24 to 48 hours is appropriate after successful extubation. For the patient failing extubation, laryngoscopic findings should drive the decision for early tracheostomy or for a second extubation attempt. Vocal cord function sufficient to maintain the airway must be documented before tracheal decannulation.

Some hoarseness or other vocal change is fairly common early postoperatively and can represent intubation trauma rather than recurrent nerve injury. Intubation-related vocal changes improve rapidly postoperatively. Hoarseness that persists at the first outpatient office visit deserves diagnostic laryngoscopy. If vocal cord motion is impaired, consideration should be given to confirmation by a second, independent observer. Voice rest and aspiration precautions should be instituted, and the patient is followed carefully. When symptoms resolve or plateau, laryngoscopy is repeated to document the level of functional return. Interventions such as vocal cord injection are not undertaken until function has

clearly stabilized. Nerve dysfunction at 1 year is likely to be permanent.

Superior laryngeal nerve external branch dysfunction typically is more subtle than recurrent nerve injury, and injury rates are not as well established. Referral for comprehensive evaluation of vocal function is appropriate for persistent voice symptoms despite good vocal cord movement or for patients whose livelihoods require normal voices (e.g., a professional singer or storyteller). The impact of routine intraoperative nerve monitoring on recurrent and external branch nerve injury rates is unclear.

Permanent hypoparathyroidism (requirement for calcium supplementation more than 1 year postoperatively) should be uncommon (< 2%) after bilateral thyroid resections. Up to 10% of patients may have transient hypocalcemia that requires treatment, especially with Graves disease or synchronous lymphadenectomy. Resolution is usually fairly rapid (< 6 weeks). Autotransplanted parathyroid tissue is usually functional within 12 weeks postoperatively. Diagnosis and management of hypocalcemia have already been discussed [see Early Postoperative Care, Bilateral Resections, above].

OUTCOME EVALUATION

Surgeons performing thyroidectomies should track their individual rates of nerve and parathyroid injuries along with wound infections and neck hematomas. Participation in a registry system such as the National Surgical Quality Improvement Program (NSQIP) facilitates recognition of nonspecific complications (e.g., urinary tract infection) and system parameters (e.g., length of stay).

10 PARATHYROID DISEASES AND OPERATIONS

Patrick B. O'Neal, MD, Atul Gawande, MD, MPH, Francis D. Moore Jr, MD, and Daniel T. Ruan, MD

Anatomy/Embryology

The parathyroid glands arise during the fourth and fifth weeks of gestation from branchial pouches III and IV. The superior glands descend into the neck from branchial pouch IV, whereas the inferior glands descend into the neck from branchial pouch III. In general, the superior glands settle 1 cm superior to the inferior thyroid artery in a posterior position to the thyroid gland, and the inferior glands settle at the lower pole of the thyroid gland in a posterolateral position. The superior and inferior parathyroids are consistently located posterior and anterior to the recurrent laryngeal nerve, respectively.

The parathyroid glands can be found in ectopic locations. Approximately 60% of parathyroids on reoperation are not located in the typical locations. The inferior glands have a higher propensity for this in comparison with the upper glands. Common ectopic locations of the inferior glands at reoperation include the thymus (46%), within the thyroid itself (7%), undescended (4%), and the carotid sheath (1%). Common ectopic locations of the superior glands include the posterior superior mediastinum (40%), the tracheoesophageal groove (17%), within the thyroid (1.5%), and the carotid sheath (1.5%). Of note, the posterior and anterior relation to the recurrent laryngeal nerve is typically preserved in superior and inferior ectopic glands, respectively.

Most commonly, there are four parathyroid glands; however, the incidence of supernumerary glands is around 13%. All four glands derive their blood supply from the inferior thyroid artery. Venous drainage is by the venous network of the thyroid capsule and/or venous pedicles of the thyroid body. The glands are often found embedded in fat. When dissected, normal parathyroid glands have a flat triangular shape with a mustard hue whereas pathologic parathyroids are plump with a reddish-brown hue resembling a grape.

The recurrent laryngeal nerves innervate all intrinsic muscles of the larynx except the cricothyroid muscles. These nerves arise from the vagus nerves in the chest and travel upward on either side of the trachea through the tracheoesophageal groove. They usually cross posterior to the inferior thyroid arteries but can pass anteriorly. They will then cross posterior to or through the Berry ligament to insert into the cricothyroid muscles. Caution should be taken when dissecting this area as the nerve may branch into an anterior motor branch and a posterior sensory branch. One can easily mistake a posterior sensory branch as the only branch and ligate the motor branch causing ipsilateral vocal cord paralysis.

Function

The primary function of the parathyroid glands is to maintain calcium homeostasis within the body. Calcium concentrations in the serum are directly regulated by a sensitive calcium-sensing receptor that is highly expressed on the surface of the parathyroid cells. When ionized calcium is bound within this receptor, release of parathyroid hormone (PTH) is inhibited. In contrast, when ionized calcium levels are low, fewer receptors are bound, and production of PTH is stimulated. PTH is an 84-amino acid protein with multiple effects on calcium homeostasis. PTH increases osteoclast and osteoblast activity, leading to the net release of calcium from bone stores as clastic activity is more affected than blastic activity. Furthermore, PTH increases gastrointestinal absorption and renal calcium retention, primarily in the proximal tubule and the loop of Henle. Lastly, PTH increases renal hydroxylation of 25-hydroxyvitamin D. In addition to increasing serum calcium, PTH also decreases serum phosphate and increases renal bicarbonate excretion.

Dysfunction

Primary hyperparathyroidism (PHPT) results from the inappropriately high secretion of PTH causing hypercalcemia. This is thought to be caused by the spontaneous loss of calcium-sensing receptors in parathyroid tissue. This may be caused by dysfunction in one or multiple parathyroid glands. Approximately 90% of PHPT is caused by adenomas, which can be multiple in approximately 3 to 8% of cases. In contrast, 9% of PHPT is attributable to four-gland hyperplasia and approximately 1% is the result of parathyroid carcinoma. As much as 3% of PHPT is associated with the multiple endocrine neoplasia (MEN) syndromes. PHPT is not caused by renal disease, a history of lithium use, or gastrointestinal malabsorptive syndromes.

Although PHPT has traditionally been considered to manifest itself by hypercalcemia in the setting of excessive PTH secretion, a less common manifestation of PHPT that has only minimal, intermittent, or even the absence of hypercalcemia is now being recognized. As many as 15% of patients with PHPT will have "normocalcemic hyperparathyroidism." As noted, these patients will have elevated PTH levels but will not have persistently elevated calcium levels. In fact, some may have calcium levels that are consistently within a normal range. They will still exhibit, however, the destructive complications of PHPT. Because one cannot use hypercalcemia as a diagnostic tool for this entity, diagnosis is difficult. Typically, PTH levels are inappropriately elevated in the

presence of PHPT complications. Vitamin D deficiency and benign familial hypocalciuric hypercalcemia should be excluded prior to the diagnosis. Additionally, evidence suggests that calcium-loading challenges may assist in identifying these patients. In most normal patients, an oral calcium load has been shown to suppress serum PTH levels by 70% or more, whereas in patients with normocalcemic PHPT, this is usually not the case. Nonetheless, this is not a perfect test and cannot be used alone to identify these patients.

Secondary hyperparathyroidism (SHPT) occurs from the physiologic response to low serum calcium levels of nonparathyroid origin. Although the pathophysiology of SHPT is complex, it is most commonly caused by chronic renal failure, which interferes with vitamin D metabolism, which in turn leads to decreased calcium absorption from nutritional sources. Other causes include “hungry bone syndrome,” sprue, chronic vitamin D deficiency, and aluminum toxicity from hemodialysis. Generally, hypercalcemia is not a characteristic of this disease.

Tertiary hyperparathyroidism (THPT) is the long-term consequence of prolonged SHPT after the cause is corrected. It results in autonomously elevated PTH concentrations as a result of the loss of calcium-sensing receptors in parathyroid tissue. The net result of THPT is elevated serum calcium. The typical scenario is the patient with SHPT attributable to end-stage renal disease who undergoes renal transplantation. In this condition, all four glands are treated as hyperplastic glands.

Parathyroid carcinoma is a very rare cause of hyperparathyroidism. It often results in markedly elevated levels of both PTH and calcium. Complications of hyperparathyroidism are more common with parathyroid carcinoma. The incidence of kidney stones is over 50%, whereas severe bone disease is observed in as many as 90% of patients. These lesions are more likely palpable than benign hypersecreting glands, and on gross inspection, they exhibit invasive features. Histologically, parathyroid carcinoma shows features of capsular and vascular invasion, cellular mitoses, thick fibrous bands separating tumor lobules, and a trabecular pattern. Of course, the hallmark of parathyroid carcinoma is its invasive nature. Thirty percent of patients will have nodal metastases on presentation, and the 5-year survival rate approximates 60% with treatment. Posttreatment, recurrent hypercalcemia is a good marker for local recurrence or new metastases.

Complications of Hypercalcemia

 The normal serum calcium level is 9 to 10.5 mg/dL. Dysregulation of calcium homeostasis has profound effects on patient well-being. On questioning, patients often complain of a general sense of poor physical performance. This includes symptoms of depression, fatigue, muscle weakness, cognitive deficits, and forgetfulness. In addition, patients may present with gastrointestinal complaints, particularly constipation and gastroesophageal reflux.

More seriously, 30% of patients with PHPT will develop nephrolithiasis and 15% of patients will develop osteoporosis. Occasionally, patients can develop severe osteodystrophy, resulting in bone pain, osteomalacia, pathologic fractures, and osteitis fibrosa cystica (brown tumors of bone).

Interestingly, there is now a growing literature implicating hyperparathyroidism in atherosclerotic disease. Evidence for

this includes studies showing increased blood pressure, arterial stiffness, and intima/media thickness in patients with PHPT as well as derangements in a number of metabolic processes leading to the development of cardiovascular disease, including dyslipidemia and impaired glucose metabolism. In fact, cardiovascular complications are the most common cause of death in both treated and untreated patients with PHPT. Estimates of mortality resulting from cardiovascular disease in patients with PHPT range from 53 to 68%. This includes death from myocardial infarction, stroke, and heart failure. Epidemiologic studies suggest that the life expectancy in patients with PHPT is lower than that in matched controls.

Evaluation of Primary Hyperparathyroidism

Although often unrevealing, a thorough history and physical examination should be performed. This may reveal symptoms or complications of hyperparathyroidism that may need to be addressed. Additionally, the information obtained may reveal the need to evaluate patients for familial causes of hyperparathyroidism, particularly the MEN syndromes. Physical examination may reveal a palpable neck mass that may alert the surgeon to the possibility of malignancy. Physical examination findings in chronic PHPT include band keratopathy and intraoral tumors.

Laboratory workup should include serum calcium and PTH levels and 24-hour urinary calcium levels to rule out familial hypocalciuric hypercalcemia. As noted earlier, patients with PHPT typically have elevated serum PTH and serum calcium levels but PTH may fluctuate and near normocalcemic variants have been reported. In these patients, one will see a persistently elevated (as opposed to suppressed) PTH level despite near normal serum calcium or high normal serum calcium levels. Patients with PHPT may have normal but often have high 24-hour urinary calcium levels as the kidneys surpass their threshold for calcium resorption. Patients with benign familial hypocalciuric hypercalcemia will have low 24-hour urinary calcium levels. Additionally, patients with familial hypocalciuric hypercalcemia generally have mildly elevated serum calcium levels. Benign familial hypocalciuric hypercalcemia can be excluded in patients with a history of normal serum calcium levels in the distant past. Hyperparathyroid patients are typically hypophosphatemic, and alkaline phosphatase may predict high-turnover bone disease. 25-Hydroxyvitamin D should be checked to exclude vitamin D deficiency.

Localization studies have improved dramatically over recent years, allowing for progressively fewer invasive surgical options. Because 80% of patients with PHPT have a single adenoma, preoperative localization studies allow far less extensive neck dissection. The mainstays of localization studies are ultrasonography and sestamibi scanning. Ultrasonography has a sensitivity of 79%. Sestamibi scanning has a sensitivity of 88%. When these two modalities are combined, sensitivity increases to greater than 90%. Sestamibi scanning works on the premise that both thyroid and parathyroid absorb tracer but that, as a result of increased blood flow in the thyroid, thyroid tracer washes out more quickly (minutes to 2 hours), allowing for visualization of enlarged parathyroid

glands. When comparing early and delayed sestamibi images persistent uptake may be seen in the delayed images at the location of pathologic parathyroid glands. Occasionally, these imaging modalities are insufficient. The advent of four-dimensional computed tomographic (CT) scanning has allowed for the localization of many allusive parathyroid glands. Other options include venous PTH sampling. Although localization studies are useful for surgical planning, they should not be used to establish the biochemical diagnosis.

Treatment

Treatment algorithms depend on the pathology causing hyperparathyroidism. In general, PHPT is treated surgically with removal of all hyperfunctioning parathyroid tissue. There is agreement that all symptomatic disease should be treated surgically. However, the indications for the treatment of asymptomatic disease are less clear-cut. These indications receive a great deal of scrutiny and are periodically revised by National Institutes of Health consensus conferences in response to evolving data. Currently, surgery is recommended for asymptomatic patients with serum calcium levels 1.0 mg/dL above the upper limit of normal, a glomerular filtration rate less than 60 mL/min, T scores less than -2.5 at any site and/or previous fracture fragility, or age less than 50 years. T score refers to the number of standard deviations above or below the normal bone mineral density a person's own bone mineral density is. Normal is defined by a T score above -1. Osteopenia is defined by a T score between -1 and -2.5. Osteoporosis is defined by a T score less than -2.5. It is expected that these criteria for surgery in the asymptomatic patient may be further revised as new data elucidate other complications of hyperparathyroidism, particularly atherosclerotic disease.

For individuals who cannot undergo surgery, patients with persistent hyperparathyroidism in which hyperfunctioning tissue cannot be found, and patients with hypercalcemic crisis, a number of medical therapies may improve hypercalcemia. These include hydration with normal saline, loop diuretics, bisphosphonates, calcitonin, mithramycin, and calcium receptor agonists. SHPT generally is not considered a surgical disease. Instead, these patients are treated with calcimimetics, calcium, and vitamin D replacement. Rarely, with failure of medical management, surgery may be considered. In this case, indications for surgery may include severe pruritis, musculoskeletal pain, renal osteodystrophy, and calciphylaxis.

Tertiary hyperthyroidism is primarily a surgical disease. Because all parathyroid tissue is hyperfunctioning in these patients, the preferred operation is four-gland parathyroidectomy with autotransplantation of half of a single gland or subtotal parathyroidectomy. In the latter case, a parathyroid remnant roughly the size of a normal parathyroid gland is left in situ.

Parathyroid carcinoma absolutely requires surgery if cure is to be achieved. In this case, the operation of choice is en bloc resection of the malignant parathyroid tumor with the overlying musculature and ipsilateral thyroid lobe. Additionally, local recurrences and localized distant metastases should be treated surgically. Systemic chemotherapy and radiation have

minimal efficacy and are considered palliative interventions in this context.

Surgical Technique

OPERATIVE PLANNING

Patients with profound hypercalcemia (serum calcium ≥ 12.5 mg/dL) or mild to moderate renal failure should be hydrated and given furosemide before operation. On rare occasions, such patients require additional treatment—for example, administration of bisphosphonates, mithramycin, or calcitonin. Bisphosphonates should be used with caution as they can exacerbate postoperative hypocalcemia. Electrolyte abnormalities, such as hypokalemia, should also be corrected prior to this elective surgery. Optimally, patients should have any anticoagulation held perioperatively and should be deemed safe from a cardiopulmonary standpoint for anesthesia.

We recommend either bilateral exploration or focused exploration with intraoperative PTH assay for most patients undergoing initial operations for primary sporadic hyperparathyroidism. The latter approach can be taken only when the abnormal gland has been identified by sestamibi scanning and/or ultrasonography. For patients with familial primary or secondary hyperparathyroidism, bilateral exploration is recommended because most of these patients have multiple abnormal parathyroid glands.

Other preoperative localization studies (e.g., magnetic resonance imaging [MRI] and CT scanning) are generally unnecessary: they provide useful information in about 75% of patients but are often not considered cost-effective, because an experienced surgeon can treat hyperparathyroidism successfully without imaging 95 to 98% of the time. Such studies are, however, essential when reoperation for persistent or recurrent hyperparathyroidism is indicated. High-resolution, four-dimensional CT scanning is particularly useful for patients in this setting. Patients requiring reoperation should be considered for direct or indirect laryngoscopy before operation to evaluate vocal cord function.

Optimum exposure of the parathyroid glands is facilitated by placing a soft roll transversely across the scapula and a support under the occiput; in this way, the neck is gently extended and the thyroid or parathyroids can assume a more anterior position. This positioning also facilitates identification of the recurrent laryngeal nerve by placing it under slight tension. The head must be supported to prevent postoperative posterior neck pain. Care also is taken to ensure that no body parts are exposed to undue pressure. The skin is prepared with betadine or chlorhexidine.

OPERATIVE TECHNIQUE

General Troubleshooting

Safe parathyroid operations require good visualization of central neck structures. Therefore, the field should be bloodless and well illuminated, preferably with the use of a headlamp. Operating telescopes ($\times 2.5$ or $\times 3.5$ magnification) are also recommended because the recurrent laryngeal nerve can be difficult for some to visualize without magnification. If bleeding occurs, surgeons should avoid grasping or clamping a poorly visualized vessel. A bleeding vessel should be clamped only after it is precisely identified and inclusion

of the recurrent laryngeal nerve is excluded. Preoperative localization studies should be available in the operating room to guide the dissection.

Step 1: Incision and Mobilization of Skin Layers

A transverse incision paralleling the normal skin lines of the neck is made approximately 1 cm caudad to the cricoid cartilage [see Figure 1]. Preferably, this incision can be placed completely within a skin crease. Such creases can be marked in the preoperative setting with the patient sitting upright with a neutral neck position. As a rule, the incision should be about 4 to 6 cm long and should extend from the anterior border of one sternocleidomastoid muscle to the anterior border of the other. Either sharp dissection or electrocautery can be used to dissect through the subcutaneous layer and platysma muscle. Straight Kelly or small Kocher clamps are placed on the dermis for retraction, which facilitates the creation of flaps in the avascular plane located just deep to the platysmal muscle and anterior to the anterior jugular veins and their branches. These subplatysmal flaps are made in the cephalad direction up to the level of the thyroid cartilage notch and caudally down to the suprasternal notch. Self-retaining retractors are then applied.

Troubleshooting Placing the incision approximately 1 cm below the cricoid locates it precisely over the thyroid isthmus. The course of the incision should conform to or overlay the natural skin creases. The length of the incision should be modified as necessary for good exposure. Patients with short, thick necks or large, low-lying tumors require longer incisions. The lateral margins of the incision should be at equal distances from the midline, and the overall shape of the incision should be symmetrical. Flaps must be created using anterior traction and taking care not to perforate the skin.

Step 2: Midline Dissection and Mobilization of Strap Muscles and Thyroid

The thyroid gland is exposed via a longitudinal midline incision through the deep cervical fascia between the strap

Figure 1 The initial incision is made 1 cm below the cricoid cartilage and follows normal skin lines. A sterile marking pen is used to mark the midline of the neck, the level of the incision, and the lateral borders of the incision. A 2-0 silk tie is pressed against the neck to mark the incision site itself.

muscles. Because the strap muscles are farthest apart low in the neck, the incision is begun at the sternal notch and extended upward to the thyroid cartilage [see Figure 2].

On the side where the suspected parathyroid adenoma is located, the more superficial sternohyoid muscle is separated from the underlying sternothyroid muscle by blunt dissection using a Kitner sponge. This typically does not cause bleeding and should extend posterolaterally until the ansa cervicalis becomes visible on the lateral edge of the sternothyroid muscle and on the medial side of the internal jugular vein. The sternothyroid muscle is then dissected free from the thyroid and the prethyroidal fascia with electrocautery until the middle thyroid vein or veins are encountered laterally.

The thyroid is retracted anteriorly and medially and the carotid sheath laterally; this retraction places tension on the middle thyroid veins and helps expose the area posterolateral to the thyroid, where the parathyroid glands and the recurrent laryngeal nerves are situated. The middle thyroid veins are ligated with sutures or with a hemostatic device to mobilize the thyroid and provide exposure behind the superior portion of the thyroid lobe [see Figure 3].

Troubleshooting Separation of the sternohyoid muscle from the sternothyroid muscle improves exposure of the operative field and does not worsen postoperative morbidity. The middle thyroid veins should be dissected free to prevent injury to the recurrent laryngeal nerve prior to their ligation. It is always safest to mobilize tissues parallel to the recurrent laryngeal nerve rather than transversely across its anticipated course. If the exposure is so limited that the strap muscles have to be divided, this should be done horizontally and high enough in the neck to preserve innervation to the bulk of the muscles. These muscles can be closed with interrupted figure-of-eight 2-0 absorbable sutures, holding the muscle apposed as the sutures are taken to prevent shredding. The neck can be gently flexed or held in a neutral position at this late stage of the operation to facilitate muscle approximation.

Step 3: Identification of Upper Parathyroid Glands

Dissection is continued superiorly, laterally, and posteriorly with a small Kitner sponge on a clamp. This maneuver can be performed with minimal bleeding when done gently. The superior thyroid artery and veins are identified by retracting the thyroid inferiorly and medially. The tissues posterolateral to the upper lobe of the thyroid and medial to the carotid sheath can be mobilized caudally to the cricothyroid muscle; the recurrent laryngeal nerve enters the larynx just posterior to the Berry ligament at this craniocaudal level [see Figure 4]. Berry ligament refers to the lateral ligament suspending the thyroid to the trachea. It is attached to the inferior margin of the cricoid cartilage cornu and extends inferomedially onto the trachea. At the level of the cricoid cartilage, the mean distance between the attachment of the ligament to the cricoid cartilage and the recurrent laryngeal nerve is 1.9 mm. This is the most common location of recurrent laryngeal nerve injury. Caution should be taken when dissecting caudal to the cricoid cartilage in this region, where the recurrent nerve can be encountered.

The tissues posterior and lateral to the superior pole can be easily swept by blunt dissection away from the thyroid gland medially and anteriorly and away from the carotid sheath

Figure 2 To expose the thyroid, a midline incision is made through the superficial layer of deep cervical fascia between the strap muscles. The incision is begun at the suprasternal notch and extended to the thyroid cartilage.

laterally. The upper parathyroid gland is often identified at this time near the level of the cricoid cartilage situated posterior to the recurrent laryngeal nerve.

Step 4: Identification of Recurrent Laryngeal Nerves and Lower Parathyroid Glands

When the thyroid lobe is further mobilized and retracted anteromedially, the lower parathyroid gland is often found anterior to the recurrent laryngeal nerve and inferior to where the inferior thyroid artery crosses the recurrent laryngeal nerve [see Figure 5]. The carotid sheath is gently retracted laterally, and the thyroid gland is retracted anteriorly and medially. This retraction puts tension on the inferior thyroid artery and consequently on the recurrent laryngeal nerve, thereby facilitating the identification of the nerve. The recurrent laryngeal nerve is situated more medially on the left in

the tracheoesophageal groove and more obliquely on the right. As such, it can be more susceptible to accidental injury on the right side. Dissection should proceed cephalad along the lateral edge of the thyroid. Fatty and lymphatic tissues loosely attached to the thyroid capsule are swept from it with a Kitner sponge on a clamp, and small vessels are ligated. No tissue should be transected until one is sure that it is not the recurrent laryngeal nerve. Some find it helpful to use a nerve monitoring device for this portion of the dissection.

Troubleshooting The upper parathyroid glands are usually situated on each side of the thyroid gland just posterolateral to where the recurrent laryngeal nerves enter the cricothyroid muscle [see Figure 4 and Figure 5]. Because the recurrent laryngeal nerve enters the larynx posterior to the cricothyroid muscle at the level of the cricoid cartilage, caution should be taken when dissecting caudal to this area.

The right and left recurrent laryngeal nerves should be preserved during every parathyroid operation. Although both nerves enter at the posterior medial position of the larynx in the cricothyroid muscle, their courses vary considerably. The right recurrent laryngeal nerve takes a more oblique course than the left recurrent laryngeal nerve and may pass either anterior or posterior to the inferior thyroid artery. In about 0.5% of persons, the right recurrent laryngeal nerve is non-recurrent and may enter the thyroid from a superior or lateral direction. On rare occasions, both a recurrent and a non-recurrent laryngeal nerve may be present on the right. The left recurrent laryngeal nerve almost always runs in the tracheoesophageal groove because of its deeper origin within the thorax as it loops around the ductus arteriosus. Recurrent laryngeal nerves often branch before entering the larynx; the left nerve is more likely to do this. Although all nerve branches should be preserved, the motor fibers of the recurrent laryngeal nerve are usually in the most medial branch.

It is helpful to remember that the recurrent laryngeal nerves are supplied by a small vascular plexus and that a tiny vessel runs parallel to and directly on each nerve, which contrasts with the white color of the nerve [see Figure 4]. In young persons, the artery usually is readily distinguished from the recurrent laryngeal nerve. However, in older persons with

Figure 3 The middle thyroid veins are divided to give better exposure behind the superior portion of the thyroid lobe.

Figure 4 The recurrent laryngeal nerve enters the cricothyroid muscle at the level of the cricoid cartilage, first passing through the Berry ligament.

arteriosclerosis, the white-appearing artery may be mistaken for the nerve, and caution should be taken. Lateral traction on the carotid sheath and medial and anterior traction on the thyroid gland place tension on the inferior thyroid artery; this maneuver often helps identify the recurrent laryngeal nerve where it courses lateral to the midportion of the thyroid gland. It is usually safest to identify the recurrent laryngeal nerve low in the neck and then to follow it to where it enters the cricothyroid muscle through the Berry ligament. Sometimes the recurrent laryngeal nerves can be palpated through

the surrounding tissue in the neck; they feel like a taut ligature of approximately 2-0 gauge.

About 85% of people have four parathyroid glands, and in about 85% of these persons, the parathyroids are situated on the posterior lateral capsule of the thyroid. Normal parathyroid glands measure about $3 \times 3 \times 4$ mm and are light brown in color. The upper parathyroid glands are more posterior and more constant in position (at the level of the cricoid cartilage) than the lower parathyroid glands, which typically are more anterior (on the posterolateral surface of the thyroid

Figure 5 The upper parathyroid glands are usually situated on either side of the thyroid at the level where the recurrent laryngeal nerve enters the cricothyroid muscle. The lower parathyroid glands are usually anterior to the recurrent laryngeal nerve and inferior to where the inferior thyroid artery crosses this nerve.

gland). Both the upper and the lower parathyroid glands are supplied by small branches of the inferior and superior thyroid arteries in most patients. About 15% of parathyroid glands are intrathyroidal, and about 1% are intrathyroidal. Other abnormal sites for the parathyroid glands are (1) the carotid sheath, (2) the anterior and posterior mediastinum, and (3) anterior to the carotid bulb or along the pharynx (undescended parathyroids).

The upper parathyroid glands are usually posterolateral to the recurrent laryngeal nerve at the level of the Berry ligament. When the upper parathyroids are not found at this site, they often can be found in the tracheoesophageal groove or in the posterior mediastinum along the esophagus. The lower parathyroid glands are almost always situated anterior to the recurrent laryngeal nerves and caudal to where the recurrent laryngeal nerve crosses the inferior thyroid artery; they may be surrounded by lymph nodes. When the lower parathyroids are not found at this site, they usually can be found in the anterior mediastinum (typically in the thymus or the perithymic fat).

Step 5: Parathyroid Resection

Abnormal parathyroid glands are then removed. In about 80% of patients with PHPT, one parathyroid gland is abnormal; in about 15%, all glands are abnormal (diffuse hyperplasia); and in about 5%, two or three glands are abnormal and one or two are normal. Parathyroid cancer occurs in about 1% of patients with PHPT.

Troubleshooting In some patients, parathyroid tumors and hyperplastic parathyroid glands are difficult to find. If this is the case, the first step is to explore the sites where the parathyroids are usually located, near the posterolateral surface of the thyroid gland within 1 cm of the point where the inferior thyroid artery crosses the recurrent laryngeal nerve. Typically, the upper and lower parathyroid glands are located posterolateral and anteromedial to the recurrent nerve, respectively. When a lower gland is missing from the usual location, it is often intrathyroidal in the upper mediastinum or lower neck. Approximately 15% of parathyroids are found within the thymus. If an upper parathyroid gland cannot be located, one should look not only far behind the thyroid gland superiorly but also in a paraesophageal position down into the posterior mediastinum. A thyroid lobectomy should be done on the side where fewer than two parathyroid glands have been located and no abnormal parathyroid tissue has been identified, and the preoperative consent should prepare patients for this possibility. The carotid sheath and the area posterior to the carotid, as well as the retroesophageal area, should also be explored for unidentified upper parathyroids. In rare cases, there may be an undescended parathyroid tumor anterior to the carotid bulb.

Although we do not recommend routine biopsy of more than one normal-appearing parathyroid gland, we do recommend taking a small biopsy of all normal parathyroid glands when no abnormal parathyroid tissue can be found. This can be done by placing a small clip across the apex of the gland followed by sharp dissection; this achieves good hemostasis without devascularizing the gland and permanently marks it for future reference. When four normal parathyroid glands are found in the neck, the fifth (abnormal) parathyroid gland

is often in the mediastinum. To minimize the risk of recurrent nerve injury during removal of identified parathyroids, dissection should be directly on the surface of the capsule without disruption. The risk of permanent hypoparathyroidism or injury to the recurrent nerve should be less than 2%.

Step 6: Closure

The strap muscles are approximated with interrupted 3-0 Vicryl sutures, and an opening is left in the midline at the suprasternal notch to make any bleeding that occurs more evident and to allow the blood to exit the central neck. The platysma is reapproximated with interrupted absorbable sutures. The skin is then closed using a deep dermal absorbable stitch, and either a skin adhesive or sterile tape is applied on the epidermis.

SPECIAL CONCERNS

Four-Gland Parathyroidectomy for Hyperplasia

This procedure will render a patient permanently hypocalcemic. We prefer to leave a remnant of the most normal-appearing parathyroid gland in situ. Alternatively, autotransplantation can be done by mincing the most normal parathyroid into 1 mm cubes and placing it in a pocket inside the sternocleidomastoid muscle, subcutaneous tissue, or forearm muscle. Clips can be placed in this location to aid in localization should a second resection become required.

Parathyroid Cancer

Parathyroid lesions that grossly extend into neighboring structures should prompt suspicion of malignancy. Such lesions should be removed en bloc with the ipsilateral thyroid lobe by hemithyroidectomy. On rare occasions, parathyroid cancers may invade the trachea or the esophagus. As much as 5 cm of the trachea can be resected safely, without impairment of the patient's voice. If the invasion is not extensive and is confined to the anterior portion of the trachea, a small section of the trachea that contains the tumor should be excised, and a tracheostomy may be placed at the site of resection. If the invasion is more extensive or occurs in the lateral or posterior portion of the trachea, a segment of the trachea measuring several centimeters long is resected, and the remaining segments are reanastomosed. To prevent tension on the anastomosis, the trachea should be mobilized before resection, the recurrent laryngeal nerves should be preserved and mobilized from the trachea, and the mylohyoid fascia and muscles should be divided above the thyroid cartilage to drop the cartilage. Care must be taken not to injure the internal laryngeal nerves during this dissection, given that these nerves course from lateral to medial just above the lateral aspects of the thyroid cartilage. After resection, the trachea is reapproximated with 3-0 Maxon sutures. One or two Penrose drains should be left near the resection site to allow air to exit. The drains are removed after several days, when there is no more evidence of air leakage.

If the esophagus is invaded by tumor, the muscular wall of the esophagus can be resected along with the tumor, with the inner esophageal layer left in place. If the recurrent nerve is surrounded or invaded by tumor, it is known that it can be dissected free, even with a slight coating of tumor, without adversely affecting the patient's cancer prognosis. However,

preoperative direct laryngoscopy or the use of nerve monitoring can allow the surgeon to determine whether the nerve is still functional prior to this dissection by testing proximal to the point of invasion. Knowledge that the nerve is not functioning can then be used to more aggressively resect the tissue in the ipsilateral paratracheal space, including the nerve. In the absence of nerve testing, careful observation can reveal a full, white nerve proximal to the tumor but a collapsed, gray nerve distal to the tumor, in which case, a complete interruption by the tumor can be inferred. In general, a recurrent laryngeal nerve that is functioning normally preoperatively also should be functioning postoperatively.

POSTOPERATIVE CARE

SCORE Patients with hyperparathyroidism should have values for serum calcium, phosphorus, and PTH checked in follow-up to evaluate for the possibility of persistent or recurrent hyperparathyroidism. Persistent hyperparathyroidism is considered when hypercalcemia in the setting of elevated PTH levels occurs within 6 months of surgery, whereas recurrent hyperparathyroidism is considered when corrected calcium and PTH levels rise again 6 months or more after surgery. As many as 10% of patients will develop recurrent hyperparathyroidism in their lifetime.

In the immediate postoperative days, patients should receive oral calcium and vitamin D as prophylaxis against hypocalcemia that can occur in the early days after parathyroidectomy. Such temporary calcium supplementation allows the remaining, normal, potentially suppressed parathyroid tissue time to upregulate. Serum calcium level checks during this period of supplementation can be used to guide withdrawal. A typical starting dose for calcium supplementation is 5 days' worth of two calcium citrate tablets four times daily.

SCORE COMPLICATIONS

The following are the most significant complications of parathyroidectomy:

SCORE 1. *Hypocalcemia.* Hypocalcemia after parathyroidectomy has a number of causes, including permanent hypoparathyroidism, transient hypoparathyroidism, and a condition referred to as hungry bone syndrome. Whereas the normal serum calcium is 9.0 to 10.5 mg/dL, anything below that would be considered hypocalcemic. Few people, however, will have symptomatic hypocalcemia with only mildly low serum calcium. Symptoms generally do not occur unless serum calcium is less than 8.0 mg/dL. Additionally, it is important to note that symptomatic hypocalcemia may be related to both the actual serum calcium level as well as its rate of fall. It is important to acknowledge how high a patient's serum calcium level was preoperatively when faced with an individual complaining of hypocalcemic symptoms.

Hypocalcemia can have a wide range of severity. Mild hypocalcemia may present with perioral numbness and tingling in the fingertips, whereas severe hypocalcemia may present with muscle cramping, spasm, and tetany. Signs of hypocalcemia include Chvostek sign, a twitching of the facial muscles when the cheek is tapped over the facial nerve. Trousseau sign is elicited by inflating a sphygmomanometer above systolic blood pressure, which causes

muscular contractions with hyperextension of the fingers in some hypocalcemic patients.

Hypoparathyroidism may arise as the result of removal, bruising, ischemic injury, or devascularization of the parathyroid glands. These injuries can be avoided by restricting any dissection to the plane nearest the thyroid capsule and then gently teasing tissue away in a posterolateral direction. As noted, hypocalcemia from hypoparathyroidism may be transient or permanent if all four glands are permanently damaged. If one is concerned about the inadvertent devascularization of normal parathyroid tissue intraoperatively, biopsy should be performed on the gland to confirm its identity and then minced pieces should be autotransplanted into a pocket in the sternocleidomastoid muscle. This tissue should not be expected to function immediately; rather, it will begin to function in a matter of weeks. Only about 50% of autotransplanted parathyroid glands survive.

Laboratory values in postoperative patients with hypoparathyroidism are likely to show low serum calcium, high phosphorus, and low or even undetectable PTH levels. It is also important to note magnesium levels as calcium replacement can be dependent on maintaining normal magnesium levels as well.

Hungry bone syndrome is a phenomenon that occurs after the PTH stimulus for bone resorption has been taken away and the bones suddenly begin to sequester calcium. The consequence of this sequestration is hypocalcemia. Additionally, phosphorus will be absorbed as well, giving low serum phosphorus levels. PTH levels may be slightly elevated here as they begin to respond to the declining serum calcium concentration. This phenomenon may last days or, sometimes, even weeks. A severe manifestation of this condition occurs in patients with osteitis fibrosa cystica. In addition to the profound hypocalcemia that may occur after parathyroidectomy, these patients may have very high alkaline phosphatase levels.

Patients treated for a single adenoma are more likely to have hypocalcemia secondary to hungry bone syndrome. This generally presents 2 to 3 days postoperatively. Patients being treated with four-gland exploration with multiple resections are more likely to experience permanent hypocalcemia. This can present within 2 hours of surgery.

Treatment and prophylaxis for hypocalcemia associated with both problems are similar; in particular, treatment consists of oral calcium, calcitriol, and magnesium when it is also low. It is our practice to give every patient for 5 days after surgery, calcium citrate four times per day and 0.5 mg calcitriol daily. If patients complain of symptoms, we ask them to take double doses. We recommend calcium citrate over calcium carbonate because calcium citrate is better absorbed. Rarely does anyone require intravenous calcium replacement as oral calcium is readily absorbed.

2. *Injury to the recurrent laryngeal nerve.* Unilateral recurrent nerve dysfunction usually results in a hoarse voice and sometimes aspiration when swallowing liquids of thin consistency. If a recurrent nerve is transected during surgery, the ends should be débrided and anastomosed with 6-0 permanent interrupted sutures. This does not restore

vocal cord function but medializes the cord and prevents atrophy. Bilateral injury to the recurrent laryngeal nerve may result in airway obstruction, which often requires tracheostomy.

3. *Bleeding.* Postoperative bleeding can be life threatening in that it can compress the trachea and result in airway obstruction. Any postoperative respiratory distress should be attributed to a neck hematoma until proven otherwise. Most bleeding occurs within 4 hours of operation, and virtually all occurs within 24 hours. Acute airway compromise from hematoma requires that the incision be opened emergently without waiting for reintubation.
4. *Infection.* This complication is exceedingly rare after parathyroidectomy. Any patient with acute pharyngitis or neck cellulitis should not undergo this procedure until the infection resolves.
5. *Seroma.* Most seromas are small and reabsorb spontaneously. Symptomatic seromas can be aspirated. Compression bandages after aspiration are helpful in some cases.
6. *Keloid.* Hypertrophic and keloid scar formation after thyroidectomy is most common in African-American patients and in patients with a history of this problem.

OUTCOME EVALUATION

The patient should have a normal voice and be normocalcemic. The overall complication rate should be less than 2%. Most patients can return to work or full activity in 1 to 2 weeks.

ALTERNATIVE TECHNIQUE

Much has been written and discussed about limiting parathyroid surgery to the exposure and removal of a single parathyroid, with consequent reduced morbidity and improved cosmesis. As experience has been gained with these techniques, we have come to realize that virtually all parathyroid surgery can be performed on an outpatient basis and that the morbidity is independent of the size of the incision or the extent of the exploration. Thus, the advantage of the “limited,” “concise,” “focused,” or “mini” parathyroid exploration may be only to those with cosmetic concerns.

Nonetheless, “mini” parathyroidectomy remains a popular operative method, limiting the necessity for a full four-gland exploration. This uses preoperative ultrasonography and sestamibi scanning to direct a more focused exploration. When both modalities have concordant results suggesting a single abnormal gland, one has a greater than 97% success with a focused parathyroidectomy that avoids bilateral neck dissection. In our experience, we have found it useful to take the time to explore the ipsilateral presumed “normal” parathyroid under these circumstances. On rare occasions, this ipsilateral gland will be abnormal and prompt the appropriate bilateral neck exploration.

Also of utility with this method is intraoperative PTH testing. Because PTH has a half-life of less than 5 minutes, comparison of a predissection PTH level to one obtained 10 minutes after excision of the adenoma should show a 50% or greater drop if all the abnormal parathyroid tissue has been removed. If this does not happen, the surgeon is generally directed to continue exploring the neck. At its inception, this assay received great attention; however, it has become

somewhat controversial whether or not it adds much when there is concordance between operative findings and preoperative imaging. Based on our experience, it does not add significantly when preoperative localization studies are concordant. When ultrasonography, sestamibi scanning, and intraoperative PTH testing are combined, patients have an approximately 98% chance of cure. This is equal in success to the results from bilateral neck surgery and four-gland exploration.

Multiple Endocrine Neoplasia Syndromes

The MEN syndromes are an inherited group of disorders characterized by the propensity for patients to develop tumors and diffuse hyperplasia of endocrine tissues. They are inherited in an autosomal dominant fashion. Because these syndromes can present with simultaneous, different endocrine tumors, treatment algorithms will be influenced by the consequences of the various presenting tumors. Additionally, prophylactic operations in these patient populations may be recommended by the high penetrance of endocrine malignancies.

MEN I is characterized by hyperparathyroidism and pituitary and pancreatic neuroendocrine tumors. Ninety percent of patients with this syndrome will have a mutation in the *MEN1* tumor suppressor gene located on chromosome 11q13. All MEN I cases will present with hyperparathyroidism, two thirds of which will be the initial manifestation of this syndrome. Most cases will occur before age 40 and will exhibit multiglandular disease. About 70% of MEN I patients will have neuroendocrine tumors of the pancreas. In this population, the tumors are usually multiple and are generally benign. Gastrinomas are the most common for MEN I patients as opposed to the general population, which has a higher incidence of insulinomas. The most common pituitary tumor is prolactinoma. The workup for these patients should routinely include serum calcium and gastrin levels, pancreatic polypeptide levels, fasting blood glucose, serum prolactin, visual field testing, and head imaging. Because hypercalcemia often exacerbates the symptoms of pancreatic neuroendocrine tumors, it is preferable to treat the hyperparathyroidism in MEN I patients first. All patients should undergo four-gland parathyroidectomy with autotransplantation of a single remnant to prevent permanent hypocalcemia. Supernumerary parathyroids are common in this group.

MEN IIa is characterized by hyperparathyroidism, medullary thyroid cancer, and pheochromocytomas. These patients generally have a mutation in the *ret* proto-oncogene on chromosome 10. This gene codes for a cell membrane receptor tyrosine kinase. Only about half of these patients will have hyperparathyroidism, again involving multiple glands. Around 70% will have pheochromocytomas, and in this patient population, they are often bilateral, multiple, and extra-adrenal. Only rarely are they malignant. Most patients will present with pheochromocytomas in the third or fourth decade of life. All of these patients will develop medullary thyroid carcinoma. Because these tumors present at a younger age than sporadic medullary thyroid carcinoma, it is recommended that patients have prophylactic total thyroidectomies at 2 years of age. All of these patients should undergo *ret*

proto-oncogene mutation screening as it is 95% sensitive for this syndrome. Additionally, serum calcium levels should be monitored, pentagastrin-stimulated plasma calcitonin can be used to follow patients for recurrence, and urinary catecholamines and their metabolites, as well as metaiodobenzylguanidine (MIBG) testing, should be considered in patients. In patients with concurrent tumors, pheochromocytomas should be treated first as operative management of other tumors may precipitate hypertensive crisis. Patients with hyperparathyroidism should undergo four-gland parathyroidectomy with single-gland remnant autotransplantation. Some kindreds have uniglandular disease and do not require such extensive surgery.

MEN IIb is characterized by medullary thyroid carcinomas (95%), pheochromocytomas (50%), neuromas (100%), and marfanoid habitus (70%). This syndrome is also associated with the *ret* proto-oncogene mutation. In these patients, medullary thyroid carcinoma presents 15 years earlier than in patients with MEN IIa and is more severe, and metastases are almost always found on presentation. The workup is the same as that for patients with MEN IIa. Again, pheochromocytomas should be treated first. Prophylactic total thyroidectomy should be performed as soon as the diagnosis of MEN IIb is made.

1 BREAST CANCER

*Stephen B. Edge, MD, FACS**

Breast cancer is the most common malignancy in women in the Western world. It is increasingly prevalent in developing countries and leads to the death of hundreds of thousands of women worldwide annually. In the United States, general surgeons treat most breast cancers. It is the responsibility of surgeons to have a thorough understanding of the principles and current practices of breast cancer surgery and care beyond surgery, including the use of imaging and other diagnostic modalities, pathology, radiation, and systemic therapy, so that surgical care is coordinated as a component of comprehensive breast cancer care.

Breast cancer refers primarily to a malignancy of the epithelium of the ductal and lobular epithelial components of the breast. Nonepithelial malignancies of the breast are much less common and include tumors of mesenchymal origin (phylloides tumors, soft tissue sarcomas) and lymphoma.^{1,2} The breast is only rarely the site of metastases from other primary malignancies. This chapter addresses only the treatment of epithelial malignancies.

Investigative Studies

HISTORY AND PHYSICAL EXAMINATION

Most women with breast cancer are asymptomatic at the time of presentation, but a complete history of breast-related symptoms and evaluation for symptoms related to metastatic disease should be performed. Particular attention should be paid to skeletal symptoms and their extent or degree and duration. A prior history of imaging findings and biopsies is important. The history should include the presence of masses or lumps in the breast, any apparent swelling, edema or thickening in the breast tissue or skin, and the presence or absence of discharge from the nipple (character, color, consistency, frequency, and mode of expression—spontaneous or elicited). The patient should be queried regarding any changes in the appearance of the nipple and the areola, the presence of scaling, eczematous changes, or peeling of the skin. The physician should also document factors related to breast cancer risk: age at onset of menarche and menopause, age at first-term pregnancy and hormone use, and a detailed family history, including the type of cancer and age at onset of all first-degree and second-degree relatives with breast cancer and ovarian cancer, on both the maternal and paternal sides of the family. If there is evidence of a syndrome of inherited susceptibility to breast and ovarian cancer or to other inherited syndromes, consideration should be made for referral to

a genetic specialist for genetic counseling and possible genetic testing. Finally, a thorough history of medication use should be recorded. In addition to common prescription medication, the patient should be queried regarding the use of supplements and other alternative medicine because of the potential effect on hormone metabolism and bleeding.

Examination of the breast and chest wall begins maneuvers to accentuate skin puckering or retraction, including extending the arms over the head and/or flexing the pectoral muscles with the hands on the patient's hips. Examination of the axilla is best performed in the sitting position. The key to successful examination of the axilla is relaxation of the muscles of the shoulder girdle. This is best accomplished with the examiner supporting the full weight of the arm abducted from the body at about an angle of 60° while palpating the axilla with the other hand. Care should be taken to examine the axilla fully underneath the pectoral muscles and along the chest wall toward the latissimus muscle. It is important to examine both axillae. The supraclavicular region should be carefully examined for the presence of enlarged lymph nodes.

The most common technique for examining the breast includes accentuating the skin of the breast by placing the patient's hand behind her head. The surgeon should develop a standard manner of examining the breast so that the entirety of both breasts is fully examined. It is generally best to begin the examination with the breast opposite the breast of concern so that this examination is not forgotten. Most examiners use a process of pushing the breast tissue back against the underlying rib cage starting at the areola and working out in a circular motion extending through the entire breast, recognizing that the breast tissues goes into the axilla. The character and size of any masses identified should be noted. The density and glandularity of the breast should be identified. It is important to compare areas of dense glandular tissue with the contralateral side to identify subtle differences in the size and density of breast tissue. Although the primary examination is performed in the supine position, the patient should be queried as to whether she perceives a palpable lesion and should be asked to reproduce the position where the lesion is best examined. Frequently, patients will identify a lesion in a position other than the supine position, and subtle findings may be identified in this way. After examination of the breast, the skin of the nipple and areola should also be carefully examined, and after warning the patient, the nipple may be compressed to elicit a discharge.

Ultrasonography is an excellent adjunct to physical examination to allow the characterization of palpable lesions as solid or cystic and to help define whether there is a specific lesion identified in areas of dense breast. Surgeons who perform ultrasonography in the office need to be fully familiar with its value and limitations and should undergo appropriate training and certification of their skill. Surgeon-performed

ultrasonography may or may not replace ultrasonography performed as part of the diagnostic breast imaging.

IMAGING

Mammography

The majority of breast cancers are detected by screening mammography. Controversy continues over the exact populations that benefit from screening mammography, but most organizations recommend mammography annually beginning at age 40 and at a younger age for women at substantial risk for increased risk of cancer.³⁻⁵

Concerning findings include new masses, asymmetry, distortion in the architecture of the breast tissue, and the presence of calcifications grouped (“clustered”) in an area of breast tissue. When an abnormality is identified, the mammogram becomes a “diagnostic mammogram,” and supplemental views are obtained in addition to the standard bilateral craniocaudad and mediolateral oblique screening views. These include accentuated positions, localized “spot” compression, and magnified settings. Any finding should be compared with previous mammograms to determine if it is new. Mammogram findings are assigned a score of 0 to 6 using the Breast Imaging Reporting and Data System (BI-RADS), with BI-RADS 4 and 5 findings requiring biopsy.⁶ Mammography detects only 80 to 90% of breast cancers and is less sensitive in women with dense glandular tissue (more common in younger women) and for lobular cancer. Suspicious physical findings (e.g., a lump or discharge) should be evaluated and biopsied even if breast imaging is normal. Mammography also has a relatively low specificity, with about 60 to 70% of all lesions requiring biopsy proving benign.

Ultrasonography

Ultrasonography is an adjunctive imaging tool to define the characteristics of a lesion identified by other imaging modalities. Ultrasonography itself is not a useful screening tool. It primarily defines whether a lesion is cystic or solid. Malignant lesions are solid and tend to have irregular borders and inhomogeneous acoustic shadowing. However, ultrasound features alone are insufficient to define if the lesion is malignant. Ultrasonography may also be used to direct needle biopsy by fine-needle aspiration (FNA), core biopsy, or vacuum-assisted needle biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) may be used in breast cancer screening and evaluation of breast cancers.⁷ MRI visualization of breast cancers requires contrast enhancement using intravenous gadolinium. Indications for breast MRI continue to evolve. MRI may detect cancers that are occult on mammography but suffers from a substantial rate of false positive findings, which leads to otherwise unnecessary biopsies and significant patient concern. MRI screening is useful in women at defined increased risk of developing breast cancer. Standard criteria in 2009 are to consider MRI screening for women with a lifetime breast cancer risk of at least 20 to 25%.⁸

The use of MRI in women with a known breast cancer has the dual purpose of screening the remainder of breast tissue and providing additional information on the extent of

the known cancer. MRI detects mammographically occult breast cancer in the contralateral breast in as many as 3% of women.⁹

MRI may assist in surgical planning. It is critical to recognize that surgical planning for cancer treatment cannot be based on the MRI finding alone and requires biopsy confirmation of any suspicious findings. Retrospective studies show that the surgical treatment planning is changed by MRI findings in as many as 20% of cases—most commonly, alteration from planned breast conservation to mastectomy. However, every study to date that has examined the question has failed to show any difference in outcomes, including local recurrence in women having presurgical MRI.¹⁰ Use of MRI may, paradoxically, unnecessarily increase the use of mastectomy. Therefore, the use of MRI in treatment planning remains controversial.

MRI may be useful in women with locally advanced breast cancer for whom neoadjuvant chemotherapy is being considered to downsize the tumor to allow breast conservation. In addition, MRI clinical response quantified by changes in enhancement and in reduction in tumor volume may be prognostic of ultimate cancer outcome.

Other Imaging Modalities

Other imaging modalities include sestamibi imaging and positron emission tomography (PET).¹¹⁻¹³ Sestamibi imaging remains investigational. PET scanning is of minimal value in evaluating the primary tumor. Other whole-body imaging of the asymptomatic patient with breast cancer is not useful in stage I and II breast cancer unless there are symptoms suggestive of metastatic disease but may be used in those with advanced disease.

Evaluation of Suspicious Findings

A breast lesion suspicious for malignancy requires tissue biopsy. Percutaneous needle biopsy is preferred over surgical excision in all circumstances. Surgical excision as a diagnostic procedure is not a justifiable alternative simply because of “patient choice” and should be performed only when needle biopsy cannot be performed for specific technical reasons, when a needle biopsy is either nondiagnostic, the result is not concordant with the imaging findings (i.e., the needle biopsy is benign, but the lesion is of high suspicion), or in highly select other cases. Technical reasons that may preclude needle biopsy include anatomic location of the lesion on mammography directly opposed to the chest wall or in the far periphery of the breast so that it cannot be visualized on stereotactic imaging devices.

FNA that provides cytology only, used extensively in the past, has largely been supplanted by core biopsy or vacuum-assisted needle biopsy that provides tissue for histologic examination. The specimens also allow performance of tumor marker studies.

Needle biopsy may be directed by direct palpation or image guidance. Lesions that are clearly palpable may be accurately localized for biopsy by palpation in the office without using imaging equipment. However, it is best to use image guidance if there is any question or if the lesion is not palpable. The choice between ultrasound, stereotactic mammographic, or MRI guidance is based on the character of the lesion

(i.e., calcifications require mammographic guidance) and the expertise and preference of the provider. In a few cases, surgical excision is required for lesions defined as benign by needle biopsy.

In addition to the “nonconcordant” finding, this includes cases where the biopsy shows the benign lesions atypical hyperplasia (ductal or lobular) or lobular carcinoma in situ. Excision is necessary in these cases because there is a small chance that there is cancer in the tissue immediately surrounding the biopsy-sampled tissue.¹⁴

Breast Cancer Management

The treatment of breast cancer requires coordination between multiple disciplines.

Surgical care cannot be done in a vacuum and must be integrated with adjuvant therapies, including radiation and systemic therapy. Although it is not mandatory that every breast cancer patient consult with specialists in each relevant discipline prior to surgery, it is incumbent upon the surgeon to ensure that the surgical care is appropriately coordinated in overall breast cancer care.

Breast cancer management addresses two major issues. The first is the treatment of the local disease in the breast itself. This is generally accomplished through surgical resection with or without radiation. The second is the adjuvant systemic therapy (chemotherapy and endocrine therapy) because any woman with invasive cancer has the risk of harboring occult microscopic metastatic disease that will ultimately lead to clinically apparent metastatic disease and death.

Decisions about treatment require accurate information on the extent of the cancer at the time of diagnosis codified using staging systems. The clinically used staging system is the TNM system of the American Joint Committee on Cancer (AJCC).¹⁵ This classifies the size and extent of the primary tumor (T), the involvement of regional lymph nodes (N), the presence or absence of distant metastases (M), and a “stage group” derived from the T, N, and M. The AJCC TNM system was recently revised for cases diagnosed beginning in 2010.

Stage should be documented in the medical record at two distinct points in treatment.

Clinical stage is the initial cancer stage used in treatment planning and includes information gleaned from the history and physical examination and any available imaging studies prior to surgery or the start of systemic or radiation therapy. Pathologic stage is the clinical stage supplemented with the findings from surgical resection. When neoadjuvant therapy is used, the extent of disease after treatment is the posttreatment stage. The degree of response to neoadjuvant therapy may be prognostic. The rules and specifics of the TNM staging system are presented in detail in the *AJCC Cancer Staging Manual* (seventh edition).¹⁵

Breast cancer management continues to evolve, and no book chapter can remain up to date. Surgeons are urged to remain current with the relevant literature and refer to guidelines in making treatment decisions. The most comprehensive guidelines that are updated at least annually are supplied by the National Comprehensive Cancer Network (NCCN) and are available at www.nccn.org.¹⁶

Noninvasive Cancer

Cancer that is confined to the lumen of the duct or lobule of the breast and has not penetrated the basement membrane is termed in situ cancer. This generally refers to ductal carcinoma in situ (DCIS) but also encompasses a benign entity called lobular carcinoma in situ (LCIS).

LOBULAR CARCINOMA IN SITU

Small uniform cells confined to the lobule of the breast characterize LCIS. It is generally a clinically and mammographically occult lesion that is identified only incidentally when a biopsy is performed for calcifications or a mass that proves to be some other benign lesion. LCIS is actually not cancer but rather is a benign lesion and does not require cancer treatment per se. The primary issue with LCIS is that it conveys an increased lifelong risk of subsequent invasive cancer quantified at 0.5 to 0.75% per year.¹⁷ In addition, when LCIS is identified on a core-needle biopsy, there is a 10 to 20% chance of DCIS or invasive cancer in the surrounding tissue; therefore, surgical excision is warranted.¹⁸

Long-term follow-up shows that the large majority of women with LCIS never develop invasive breast cancer. Therefore, ablative surgical therapy and radiation for LCIS are not necessary. Previously, LCIS was considered in and of itself an indication to consider bilateral mastectomy. However, mastectomy is generally not indicated in women with LCIS and should be performed only in the context of risk reduction for those at very high risk related to factors such as inherited susceptibility.¹⁹

Because women with a diagnosis of LCIS are at increased risk for subsequent invasive cancer, they should be counseled regarding that risk and may benefit from consultation with genetics professionals if they have a family history of breast or ovarian cancer. Women with a biopsy showing LCIS may also consider risk-reducing chemoprevention with one of the selective estrogen receptor modulators (SERM's), tamoxifen or raloxifene. These reduce the risk of subsequent invasive cancer by about 50%, with an acceptable toxicity profile.^{20,21} Raloxifene is the preferred agent in postmenopausal women.

DUCTAL CARCINOMA IN SITU

The histologic hallmark of DCIS is the presence of malignant-appearing cells confined to the lumen of the ductal system in the breast. DCIS is most often diagnosed because of the presence of calcifications clustered in one area of the breast. The calcifications suspicious for DCIS are often linear (not round), growing in a ductal distribution. The DCIS may not be confined to the extent of calcifications, and not all DCIS is manifested by calcification. Therefore, the size or extent of DCIS may not be defined by the mammographic appearance. Although DCIS occasionally presents as a mass, the presence of the mass even in the setting of a biopsy showing DCIS most often signifies that the cancer is primarily invasive.

DCIS is generally considered a precursor to invasive cancer.²² The purpose of treatment of DCIS is to prevent progression to invasive cancer with the sequelae of metastatic disease and death. However, indirect evidence suggests that not all DCIS lesions will progress to invasive cancer. Unfortunately, despite extensive research, there is insufficient

evidence to identify which DCIS lesions will progress to invasive cancer and which will remain clinically occult for the duration of a woman's life.²³ Therefore, all women diagnosed with DCIS should undergo appropriate treatment.

DCIS encompasses a spectrum of histologic subtypes. Malignant-appearing cells confined to the breast duct characterize all of these. However, the appearance ranges from bland, uniform cells growing from the wall of the duct or bridging the duct (papillary; cribriform) to cells filling the entire duct (solid). These cells also vary in nuclear morphology, ranging from low-grade, uniform-appearing nuclei to varying size and shape and large nuclei (high grade) and in the presence or absence of central necrosis within the duct. The combination of high nuclear grade and central necrosis is termed "comedo-DCIS" or "comedocarcinoma." It is possible that these subtypes of DCIS are different disease entities with different potential for progression to invasive cancer, but this is poorly understood. The clinical relevance of the DCIS subtypes is that they may have different potential for local recurrence after breast-conserving surgery, which may impact on the utility of radiation as an adjunct to wide excision. The presence of high-grade cells or comedonecrosis is not an indication of metastatic potential and does not itself warrant systemic therapy or lymph node staging.

Treatment

The overall cancer-specific survival for women with DCIS approaches 100% almost irrespective of the subtype of DCIS and the type of treatment [see Figure 1].²² Mastectomy is effective in DCIS, but in most cases, a breast-conserving approach is possible. Recurrence in the skin of the mastectomy site or on the chest wall muscle ("local recurrence") may occur, but the frequency after mastectomy for DCIS is extremely low (1 to 3%).²⁴ Most women with DCIS may be treated by surgical excision ("lumpectomy" or "wide excision") of the DCIS with some surrounding normal breast tissue to achieve a "negative margin." The choice between breast-conserving surgery (BCS) and mastectomy may be influenced by the size of the area of involvement, the size of the breast, and the location of the DCIS.

There is no specific size above which mastectomy is mandatory. Wide excision ("lumpectomy") with a generous margin of normal breast tissue can be accomplished in most women.

Large-scale randomized clinical trials in North America and Europe have demonstrated the effectiveness of BCT and the role of radiation in DCIS. The National Surgical Adjuvant Breast and Bowel Project (NSABP), the European Organization for Research and Treatment of Cancer (EORTC), and others conducted trials comparing wide excision alone versus wide excision plus radiation therapy.^{25–28} Every study demonstrated long-term overall survival approaching 100% irrespective of treatment. However, women treated with BCT had a substantial risk of recurrence in the same breast, and radiation reduced this risk. The rate of local recurrence in the NSABP study was 30% without radiation and about 12% with radiation. The size and histologic characteristics of the DCIS as well as the extent of the margin of resection also affect the risk of local recurrence.

A key factor in breast-conserving surgery for DCIS is obtaining a negative surgical margin. Because the DCIS may

extend beyond the area of calcifications seen on mammography, the rate of positive margins on the initial excision for DCIS ranges as high as 20 to 25%. Women who have a positive margin on the initial excision for DCIS must undergo repeat surgery to obtain a negative margin. On occasion, even with such "reexcision," the DCIS extends to the new margin, and some of these women ultimately require mastectomy. The definition of a "negative margin" is an area of controversy.^{29,30}

The NSABP studies used the definition of a negative margin as the absence of the ink used to paint the surgical margin on any cancer cells. However, the margin width, measured as the distance from the closest surgical margin to the DCIS, affects the risk of local recurrence, with the lowest rates among women with a full 1 cm margin.³¹ The best current evidence is that a margin of at least 2 mm is required to obtain optimal rates of local recurrence.³²

Substantial research has focused on identification of those women with DCIS who may not require radiation. Some evidence from nonrandomized series suggests that the size of the area of DCIS coupled with the nuclear grade and the width of the resection margin may identify subsets of women with DCIS for whom the risk of local recurrence is so low that radiation is not warranted.^{33,34} However, in randomized trials, there are no subsets that can be identified for whom radiation does not reduce the risk of local recurrence. Therefore, the decision to omit radiation therapy with DCIS requires careful counseling of the patient coupled with multidisciplinary input.

The standard radiation treatment is whole-breast radiation therapy to a dose of about 50 Gy potentially coupled with a 15 Gy boost to the site of the surgical excision. Because most local recurrences occur in the breast tissue close to the original DCIS, it is possible that radiation administered only to the affected region of the breast may be as effective as whole-breast radiation therapy. Techniques for administering so-called accelerated partial-breast irradiation therapy allow treatment to be delivered over a much shorter period of time (as short as 5 days), making it an attractive alternative.³⁵ However, as of 2009, there are no long-term data demonstrating the effectiveness of accelerated partial-breast irradiation in DCIS, and it remains investigational.

The choice between mastectomy and breast conservation may be difficult. It is different for women with DCIS than for those with invasive cancer primarily because those with DCIS do not face the threat of death from metastatic disease. For women with disease treatable by breast conservation, mastectomy remains a reasonable option if selected by the patient. The choice may also be influenced by the risk of developing a subsequent second breast cancer related to family history and biologically defined inherited susceptibility. An initial reaction of "just remove it" is insufficient justification for mastectomy and should be followed by careful counseling and reassurances regarding the long-term outlook for women with DCIS.

Reconstruction of the breast mound is available to most women who require or choose mastectomy for DCIS. Breast reconstruction may be performed at the same time as the mastectomy using implant techniques or tissue transfer using a variety of tissue flaps (see below).

Figure 1 Guidelines for treatment of ductal carcinoma in situ (DCIS). SNB = sentinel node biopsy.

An important issue with DCIS is that there is a risk that invasive cancer is identified in the final surgical specimen in 5 to 20% of women for whom needle biopsy showed DCIS. Invasive cancer is more likely in cases where a mass is present on imaging or physical examination. This leads some surgeons to recommend lymph node surgery in all women with DCIS. However, lymph node surgery is unnecessary in the management of DCIS because it has no metastatic potential. For women undergoing breast-conserving treatment, if an invasive cancer is identified in the final surgical specimen, lymph node staging with sentinel node biopsy (SNB) may be performed at a subsequent surgical procedure with the same level of accuracy as if done at the time of excision. Some surgeons advocate SNB in all women with DCIS, making the argument that it is cost-effective compared with a separate SNB procedure for those with invasive cancer, but there are no high-level data to support this statement. In addition, SNB carries some risk of long-term morbidity; careful evaluation on prospective studies demonstrates that women with SNB have about a 6% risk of at least mild lymphedema.^{36,37} Therefore, with breast-conserving surgery, SNB should not

be performed. Exceptions are the presence of a suspicious mass—indicative of invasive cancer—or when the DCIS is in the axillary tail of the breast, and excision may preclude subsequent SNB because of interruption of lymphatic flow to the axilla. SNB is appropriate when mastectomy is used for DCIS because of the chance that the breast harbors an invasive cancer. Mastectomy may preclude subsequent SNB; therefore, mastectomy without SNB for women with DCIS may commit those women to undergoing a full axillary lymph node dissection if invasive cancer is present.

Women who undergo radiation with DCIS may also benefit from adjuvant endocrine therapy. The NSABP conducted a clinical trial of wide excision plus radiation with or without tamoxifen.³⁸ Tamoxifen reduced the risk of local recurrence by 40%. A subsequent clinical trial not as yet reported in 2010 addresses whether an aromatase inhibitor is effective and comparable or superior to tamoxifen in reducing the rate of local recurrence in DCIS. The use of endocrine treatment in DCIS must be balanced against the toxicity of the selected drug, recognizing that endocrine therapy is not lifesaving in this situation. There are no data supporting the use of

endocrine therapy in women treated for DCIS with mastectomy.

PAGET DISEASE OF THE BREAST

An uncommon presentation of breast cancer is with eczematoid changes directly in the nipple, often with beet red and ulcerated skin in the nipple. This is due to malignant cells with a characteristic “fried egg” appearance occurring in the nipple skin or “Paget cells.” This is Paget disease of the nipple. In most cases of Paget disease, there is a cancer in the underlying breast, and the cells in the nipple may represent intraductal spread of the cancer to the nipple, although this process is poorly understood. In most cases, the underlying cancer is relatively close to the nipple and in most cases is DCIS.

Women with these changes in the nipple are often misdiagnosed as having benign skin conditions and are treated with topical agents, including steroids. If such treatments are used and the lesion does not resolve, or if there is any clinical suspicion, a biopsy of the affected skin is needed. If the biopsy shows Paget disease, then the breast should be carefully imaged by mammography supplemented by MRI if the breast is dense to search for primary tumor in the breast. If a breast lesion is found, it, too, should be biopsied.

Treatment is generally based on the type (in situ or invasive) of primary tumor in the breast and treatment of the nipple. This may be accomplished in many cases with removal of the nipple in continuity with the breast cancer, followed by radiation.³⁹ Mastectomy is still often used but may be reserved for cases with more extensive involvement.⁴⁰ Lymph node surgery is warranted only with invasive cancer. Adjuvant systemic therapy is administered by standard guidelines.

Invasive Breast Cancer

The majority of breast cancers are classified as invasive or infiltrating, characterized by the cancer invading through the basement membrane of the duct or lobule. The same properties allow basement membrane invasion may allow the malignant cells to invade surrounding blood vessels or lymphatic channels and raise a possibility of spread to distant sites. Although most have probably not spread as assessed by long-term survival without distant metastases, the treatment issues for invasive breast cancer include not only the local treatment of the breast but also the potential for distant spread and the role for adjuvant systemic drug therapy.

CLASSIFICATION

The majority of breast cancers arise from the ductal component of the terminal ductal lobular unit and are termed invasive ductal cancer. An additional 10 to 15% arise within the lobule and have a characteristic appearance of small cells infiltrating in a linear fashion through the breast stroma, termed invasive lobular cancer. Invasive lobular carcinoma carries the same risk of distant metastases as ductal carcinoma. However, lobular carcinoma may be more insidious because of the infiltrative nature of the disease, which results in a lesion more difficult to detect by mammographic or clinical means.

Certain subtypes may have a different prognosis than typical invasive ductal cancer. These include tubular carcinoma,

mucinous carcinoma, medullary carcinoma, and metaplastic carcinoma. Tubular and mucinous carcinomas may have a lower propensity for lymphatic metastases and a generally better prognosis than typical ductal cancers.^{41,42}

Medullary cancer was historically considered a cancer with a better prognosis, but the term is overused, and most tumors classified this way are high-grade cancers with a poor prognosis. Standard guidelines do not assign medullary cancer to a good prognosis subgroup.¹⁶ Because of the potential overuse of these subgroup terms, great care should be taken in making treatment decisions based on these subgroups without ensuring with the pathologist that the tumor truly is the special histology.

Inflammatory breast cancer is an infiltrating cancer characterized by skin edema and erythema encompassing over half the breast and associated with an especially high likelihood of subsequent metastases and death. It often correlates with the histologic finding of dermal lymphatics clogged by tumor cells, but the diagnosis of inflammatory cancer is only a clinical diagnosis. Skin biopsy showing dermal lymphatic involvement is not necessary to classify a cancer as inflammatory.¹⁵

Breast cancers may be better classified by biologic characteristics rather than histologic appearance. At the very least, all breast cancers should be analyzed for expression of the hormone receptors for estrogen and progesterone and the level of expression or amplification of the HER-2/*neu* gene.¹⁶ These provide key prognostic information and “predictive” information about sensitivity to specific drugs to treat breast cancer. It is expected that biologic classification of breast cancers beyond these three receptors will ultimately allow a higher degree of personalization of both local and systemic treatment.^{43,44}

The accuracy of testing for estrogen, progesterone, and HER-2 varies, and this variation impacts significantly on patient outcome. To improve this situation, national organizations have established practice standards for laboratories performing this testing.^{45,46} Pathology should be reported using structured documentation according to the templates provided by the College of American Pathologists (www.cap.org). Surgeons should be sure that testing for their patients is performed and reported in accordance with these standards.

LOCAL THERAPY OF T1 AND T2 INVASIVE BREAST CANCER

The primary goal of local therapy of breast cancer is eradication of the primary tumor to prevent progression and further dissemination of the disease [see Figure 2]. In addition, staging of the regional lymph nodes is performed to provide prognostic information and to guide systemic treatment as well as provide regional control in the common regional nodal basins.

Mastectomy versus Breast-Conserving Surgery

Historically, local treatment of breast cancer meant mastectomy. One can argue that the development of the operation of radical mastectomy was the single most important advance in the treatment of breast cancer. At the time it was developed in the late 1800s, most women presented with breast cancers that were locally advanced and were likely to progress to difficult painful and infected local problems. However, the ability to treat breast cancer effectively led to

Figure 2 Overview schema for local therapy for stage I/II breast cancer.

women presenting with smaller cancers. However, it was not until the 1970s that the so-called “halstedian” thesis, that breast cancers progressed in a stepwise fashion from the breast (local) to lymph nodes (regional) to distant disease (metastases), was proven incorrect. In the 1970s and 1980s, landmark clinical trials demonstrated that breast cancer is a systemic disease with the possibility of disseminated disease even at the smallest primary tumor and that removal of the tumor without mastectomy provided long-term outcome equivalent to mastectomy. The most significant study was the NSABP B-06 trial comparing mastectomy with lumpectomy alone and with lumpectomy plus radiation therapy.⁴⁷ Long-term follow-up on this trial demonstrated no difference in overall survival between the three groups. However, with lumpectomy alone, the cancer recurred in the same breast in as many as 40% of women. Radiation reduced this rate of local recurrence to approximately 12%. On the basis of this finding, lumpectomy plus radiation therapy became an accepted standard in the late 1980s and became widely used through the 1990s.

Breast-conserving surgery may be performed in a majority of women with invasive breast cancer. Successful BCT requires obtaining negative margins of resection around

the tumor. As with DCIS, major clinical trials testing BCT defined a negative margin as no ink on the tumor. However, in general, a minimum 2 mm margin is optimal. A specific exception may be at the chest wall, where the pectoralis fascia has been taken, and anteriorly at the skin. If a negative margin cannot be obtained with lumpectomy, including with a second or occasionally a third operation for “reexcision,” mastectomy is necessary.

Indications for mastectomy include the presence of multicentric disease in the breast—separate cancers in distinct parts of the breast separated by at least 5 cm of normal breast tissue, occurring in 2 to 5% of cases; a very large tumor in relation to the size of the breast that is not amenable to lumpectomy or does not respond sufficiently to neoadjuvant systemic therapy; and previous radiation treatments to the breast, such as with a prior breast cancer or for treatment of other cancers, such as lymphoma. Radiation may not be administered during pregnancy, but with standard sequencing of systemic and radiation after BCT, radiation is usually timed such that it is administered after delivery of the baby; therefore, BCT is possible for women presenting with breast cancer during pregnancy. In addition, mastectomy is indicated after completion of systemic chemotherapy for

inflammatory breast cancer because of the likelihood of the microscopic extent of disease both in the skin and within the breast beyond the area of known cancer.

An unusual presentation of breast cancer is with axillary lymph node involvement without the presence of a detectable primary cancer in the breast (occult breast primary tumor). If a woman has suspicious lymph nodes in the axilla, biopsy is warranted. If the histology shows an adenocarcinoma (as opposed to lymphoma or melanoma), the primary source of this metastatic deposit is almost invariably the breast, even if the hormone receptors are negative. Mammography usually shows the primary tumor, but MRI may find some of these cancers not seen on mammography.⁴⁸ However, in a few cases, even MRI will be negative, yet the source is invariably the breast. A whole-body search for another source of adenocarcinoma is not indicated. The woman should receive therapy assuming that this is a breast cancer.

In the past, mastectomy was used for all women with an occult breast primary tumor with a positive axillary node. However, recent data show that mastectomy is not necessary.

They should undergo axillary lymph node dissection and then receive adjuvant systemic therapy (chemotherapy and endocrine therapy) as appropriate based on stage and biologic features and then radiation to the breast.^{49,50}

Women who have inherited susceptibility with a mutation known in *BRCA1* or *BRCA2* also often choose mastectomy or bilateral mastectomy. The overall survival for women treated with BCT in this situation is the same as for women without inherited susceptibility.⁵¹ However, they are at increased risk for developing a second primary cancer in the same breast, a chance that approaches 50%, especially in women under age 50 at the initial diagnosis.⁵²

Radiation in Local Therapy

Mastectomy should be supplemented with radiation when the cancer is over 5 cm in size, when surgical resection margins are close or positive, or when multiple lymph nodes are involved.⁵³ The “textbook” standard is that radiation is indicated with four or more positive nodes. However, radiation should be considered even when only one to three nodes are involved based on the findings of randomized clinical trials demonstrating improved survival. Unfortunately, a major American clinical trial addressing the use of radiation after mastectomy for women with one to three positive nodes failed to accrue sufficient numbers of patients to provide an answer to this critical question.

The possible need for radiation after mastectomy may affect decisions regarding the cosmetic outcome of immediate breast reconstruction.⁵⁴ Immediate reconstruction may complicate radiation dosimetry and uniform dose delivery over the entire field and increase the volume of tissue outside the field, including the lung and heart. In addition, radiation may compromise the cosmetic result of immediate reconstruction through contracture of the scar capsule around an implant and/or contracture of tissues within an autologous tissue flap. The potential need for radiation after mastectomy should be discussed with all women having mastectomy for invasive breast cancer.

Radiation is generally administered in all cases with BCT. Radiation reduces the risk of local recurrence by as much as

70%, and this may improve survival.⁵⁵ Subset analysis of large clinical trials and limited clinical trials in women with small cancers failed to identify cancers of sufficiently small size that radiation does not reduce the risk of local recurrence.

One group in whom the omission of radiation is reasonable is women over age 70 with cancers that are hormone receptor positive, 2 cm or smaller, with clinically negative nodes. A clinical trial conducted by Cancer and Leukemia Group B (CALGB) randomized such women to lumpectomy and tamoxifen with or without radiation.⁵⁶ There was no difference in long-term survival. Local recurrence occurred in 1% with and 6% without radiation. However, the same number of women in both groups ultimately underwent mastectomy as those who had not received radiation or were most often treated with lumpectomy and radiation. Therefore, omission of radiation is reasonable in this group. A similar trial conducted in Canada for women age 50 and over demonstrated local recurrence rates of about 15% among women between age 50 and 70, lending caution to omitting radiation for younger women.⁵⁷

The standard radiation treatment after breast-conserving surgery is treatment of the entire breast to a dose of about 50 Gy, with an additional boost of radiation to the primary tumor site of about 15 Gy. Radiation treatment takes about 6 weeks of therapy and is well tolerated. Long-term serious sequelae of whole-breast radiation are uncommon.

Recent clinical research has focused on the potential for limiting the extent and time required to deliver radiation to the breast. This research is based on the finding that most recurrences occur within a short distance from the primary tumor site. Only about 15% of new events in the treated breast occur outside the area of the original tumor area and are most likely a new second primary cancer. It is hypothesized that limitation of radiation treatment only to the site of the primary cancer can provide local control equivalent to whole-breast radiation therapy. So-called accelerated partial-breast irradiation (APBI) has one major advantage: because of the technical issues in radiation dosimetry and tissue tolerance, APBI may be delivered in a much shorter time frame—generally two fractions a day over only 5 days. Another purported advantage is that if there is a second disease event in the affected breast, this may be treated by a repeat lumpectomy rather than mastectomy. However, there are no data to support this thesis.

There are a number of techniques to deliver APBI.⁵⁸ The technique with the longest-term follow-up, albeit in a limited number of patients, is multicatheter brachytherapy. This technique is cumbersome, unsightly, and seldom used. More recent alternative techniques for delivery of APBI include three-dimensional computed tomography (CT)-directed external beam radiation, brachytherapy using a radiation seed in a balloon catheter placed in the lumpectomy site, and a single intraoperative dose of radiation. These are promising technologies, but there are no long-term data from controlled clinical trials demonstrating the safety and effectiveness of these techniques.⁵⁸ Data from noncontrolled series are scant and have very short-term follow-up in a setting where, at the very least, 5-year follow-up is required. Large clinical trials are ongoing, including a study by the NSABP. Therefore, as of 2010, APBI remains investigational and whole-breast radiation therapy remains the standard.^{16,59}

Local Recurrence with Mastectomy or Breast-Conserving Surgery

Local recurrence after surgical treatment of breast cancer occurs with both mastectomy and BCT. The risk of local recurrence after lumpectomy is somewhat lower than reported in the NSABP B-06 trial. When performed by experienced surgeons with careful pathologic control, appropriate radiation, and stage-appropriate adjuvant systemic therapy, the rate of local recurrence with BCT is as low as 1 to 5%. Local recurrences are also a significant issue among women treated with mastectomy. This risk is about 2 to 5% for women with negative lymph nodes and ranges as high as 25% for women with multiple positive lymph nodes.^{60,61}

Local recurrence is a serious event whether it occurs after BCT or mastectomy. These women have a higher risk of developing distant metastases compared with women with similar-stage cancer who do not suffer local recurrence. It has previously been generally cited that radiation impacts only the risk of local recurrence and not overall survival. However, a meta-analysis of all available data for women treated with BCT and mastectomy demonstrated that radiation therapy not only reduces the risk of local failure but also improves survival.⁵⁵ The best estimate is that radiation saves one life for every four local recurrences prevented. Radiation is therefore recommended for women who have a risk of local failure over 10% regardless of the type of primary surgery.

The accepted treatment for local recurrence after BCT is mastectomy. This is because the recurrence may be multifocal and because full-dose radiation cannot be administered safely a second time because of tissue toxicity. Local recurrence after mastectomy is more difficult to treat and carries a more serious prognosis. Treatment usually includes resection of a local recurrence in the skin, muscle, or regional nodes if possible, followed by radiation to the chest wall and regional nodes. The role for additional adjuvant systemic therapy after local recurrence is uncertain, and there are no clinical trial data supporting its use. However, many oncologists will deliver additional systemic treatment based on the type of previous treatment and the nature and extent of the local recurrence.

Selection of Breast-Conserving Surgery versus Mastectomy

The decision between BCT and mastectomy is a complex and difficult one for women with breast cancer. From a technical standpoint, BCT is possible in the large majority of women with breast cancer. More than 90% of women with tumors under 2 cm in size (T1) may undergo BCT given the absolute and relative contraindications to BCT discussed above. However, many other factors in addition to the technical ability to perform BCT affect the decision. Ultimately, the individual patient is the determinant of whether or not she will have mastectomy. Her choice may be influenced by perceptions or values based on personal or family experiences, real or perceived increased risks of recurrent cancer based on family history, and other factors.

Counseling women regarding the choice of surgery is one of the most important tasks for the treating surgeon.⁶² Surgeons need to learn the skills of nondirective counseling and must incorporate other professionals and resources into their practice. Careful study of the decision-making process has shown that physicians are not necessarily fully sensitive to

their patient's concerns or to their styles of decision making.⁶³ This has led to the development of decision assistance and support tools and to the recognition of the need for multidisciplinary counseling, especially in more complex situations or those associated with questions surrounding inherited susceptibility and genetics.⁶⁴

One of the key factors in this process is the recognition that breast cancer treatment is not an immediate emergency. There are no data to support the contention that treatment initiated within a few days of diagnosis improves outcome compared with that delayed a reasonable period of time, measured in a number of weeks or even months. Women should be given the opportunity to seek additional counseling, research information on their own, and obtain second opinions if they so desire. Inclusion of professionals of other disciplines, including radiation oncology, plastic surgery, medical oncology, radiology, psychology and social support, nursing, and genetics, may be warranted.

MANAGEMENT OF THE CONTRALATERAL BREAST

Women with breast cancer have a risk of second malignancies and especially the risk of developing a contralateral primary breast cancer. Outside the setting of inherited susceptibility, the chance of developing a contralateral primary breast cancer is about 10% over 20 to 30 years.⁴⁷ Given that the average woman is in her 50s or 60s and that most of these contralateral breast cancers will be effectively treated, the risk that a woman with a breast cancer will succumb to a new contralateral breast cancer is far outweighed by both the risk of death from the current breast cancer and the long-term risk of death from other causes during the very long-term follow-up in which second cancers occur. Therefore, treatment addressing the other breast is generally not necessary.

Previously, it was believed that women with invasive lobular cancer had a much higher risk of a contralateral breast cancer compared with ductal cancer. The added risk of contralateral cancer with lobular cancer is relatively small and should have little bearing on treatment decisions.

The issues are different for women with inherited susceptibility, most notably those with mutations in *BRCA1* and *BRCA2*. They are generally younger at breast cancer diagnosis and have a higher risk of developing a second cancer. This risk appears dependent on the age at which they are diagnosed with their first breast cancer: 25 to 50% for those under age 50 at the initial diagnosis and 15 to 20% for those over age 50.⁵²

Careful counseling can largely allay a woman's fears of the impact of the risk of a second cancer. However, some women, especially those undergoing mastectomy for the index cancer, may request contralateral mastectomy. Recent observational studies demonstrate that the number of women undergoing prophylactic contralateral mastectomy increased significantly over the last decade. In New York State, about 4% of women treated with mastectomy in 1995 had a contralateral mastectomy compared with 15% in 2005.⁶⁵

LYMPH NODE STAGING IN BREAST CANCER

The presence of metastases in regional lymph nodes is a key prognostic factor used in making treatment decisions, as discussed below [see Figure 3]. In addition, removing lymph

Figure 3 Axillary surgery management schema. FNA = fine-needle aspiration; SNB = sentinel node biopsy.

nodes prevents recurrence risk in the regional lymph node basin. However, treatment of lymph nodes does not itself affect survival. Defining the involvement of regional lymph nodes requires surgical resection. No noninvasive test of the regional lymph nodes has proven insufficient sensitivity and specificity to replace surgical resection. Therefore, surgical evaluation of regional nodes remains a key component of breast cancer treatment.⁶⁶

Lymph fluid from the breast drains primarily through the axillary lymph nodes.⁶⁷ A small fraction of lymph drainage from the breast is through other pathways, including direct drainage through the supraclavicular nodes and via the internal mammary chain.⁶⁸ Because the majority of drainage is through the axilla, and because of potential morbidity of internal mammary lymph node dissection, most surgeons limit surgical evaluation of lymph nodes to the axilla.

The axilla contains an average of 15 to 20 lymph nodes extending under the axillary vein medially toward the thoracic inlet. Until the last decade, evaluating these nodes required dissection of the entire axillary contents. A safe operation, it carries substantial risk of long-term morbidity related to disruption of the lymphatic flow from the arm and permanent swelling, termed lymphedema.^{69–71} Lymphedema is a chronic lifelong condition that ranges from minimal effects to disabling swelling. The risk of lymphedema is about 10% with axillary dissection alone and substantially higher when radiation is also required after node dissection.^{37,72}

During the 1990s, the hypothesis that lymphatic drainage to the axilla could be mapped using radioactive or large colloidal particle tracers and that the first few lymph nodes identified by these mappings would define the status of the lymph nodes was tested and proven accurate.⁷³ Termed the sentinel lymph node, the first few lymph nodes can be identified and full axillary lymph node dissection limited only to those women with proven nodal metastases. Morbidity, including the risk of lymphedema, is lower with SNB than with axillary dissection, but lymphedema still may occur.³⁶

SNB is appropriate for women with clinically negative nodes. Those with clinically positive nodes are not candidates for SNB and should have full axillary lymph node dissection. If there is a question about nodes, involvement of nodes may be confirmed before surgery using ultrasound-guided needle biopsy (core biopsy or FNA).

SNB is performed by injecting radiolabeled tracer and/or vital dyes that drain to and are trapped in the initial lymph nodes in the chain. The injection is generally in the periareolar skin and under the nipple-areola complex. This identifies an average of three lymph nodes, which are then removed and examined for metastases. SNB is appropriate in virtually all women with invasive breast cancer clinically negative nodes. SNB may be performed in women with local recurrence after previous breast-conserving surgery and radiation, although the accuracy of SNB in this setting has never been tested.

BREAST RECONSTRUCTION

Women treated with mastectomy may consider reconstruction of the breast mound performed either at the time of mastectomy (immediate reconstruction) or at a later time (delayed reconstruction).⁷⁴ Immediate reconstruction is reasonable in women with early-stage breast cancer. However, the potential need for postmastectomy radiation must be considered in reconstruction planning.⁵⁴ Although satisfactory cosmetic outcomes may be obtained even with radiation to the implant, radiation increases the rate of painful scar contracture. Decisions regarding immediate breast reconstruction should be made in collaboration with the entire multidisciplinary treatment team. Conversely, delayed reconstruction requires that the woman live without the reconstructed breast for a period of 1 to 2 years and may be more difficult to perform because there is less skin remaining from the original mastectomy to be used in reconstruction.

Options for breast reconstruction include prosthetic reconstruction with an implant or “tissue expander implant” generally placed beneath the pectoralis major muscle or transfer of autologous tissue from another region in the body.⁷⁴ Implant reconstruction is generally simpler and quicker to perform but may not leave as attractive an aesthetic result. Complications of implant reconstruction include contracture around the implant (which may be exacerbated if radiation is necessary) and infection, resulting in loss of the implant. Autologous tissue reconstruction often leaves a superior cosmetic result but at the cost of more complex surgery, longer recovery, and the potential for complications at the site of the donor tissue. The most common donor sites are the rectus abdominus muscle (so-called transverse rectus abdominus myocutaneous [TRAM] flap), the more superficial fat and skin from the abdominal wall (deep inferior epigastric perforator [DIEP] flap), and the latissimus dorsi muscle flap. These flaps may be used in conjunction with complete sparing of all the skin of the breast that provides for an even better cosmetic result. In general, the nipple and areola are resected with mastectomy, but in select circumstances, such as small tumors located in the periphery of the breast, some surgeons have been experimenting with mastectomy that preserves the nipple.^{75–77}

ADJUVANT SYSTEMIC THERAPY

Women with invasive cancer also face the risk of developing distant metastases. These metastases develop from microscopic dissemination of cancer cells prior to diagnosis. Staging studies including CT, PET, and MRI are not insensitive at detecting this microscopic disease. In stage I and stage II cancer, these studies are unnecessary unless there are symptoms such as new skeletal pain or other constitutional symptoms. The chance of identifying metastatic disease is very low, and there is a substantial chance of false positive scans, requiring extensive evaluation and invasive studies.

Therefore, every woman with invasive cancer must consider whether to receive systemic adjuvant therapy to prevent the growth of this microscopic metastatic disease [see Figure 4]. The decision depends on both the estimated risk of developing metastatic disease and the degree of benefit that treatment may provide. These risks are estimated by analysis

Clinical Stage I / II (Tumor < 5 cm) Adjuvant systemic therapy: Consider in all cases: Based on • Primary tumor characteristics • Hormone receptor status • HER-2/<i>neu</i> status • Genomic profiling <u>Principles of Systemic Therapy</u> • ER positive: endocrine therapy and consider adding chemotherapy even with negative nodes • ER negative: consider chemotherapy even with negative nodes • HER-2/<i>neu</i> positive: add trastuzumab to chemotherapy
--

Figure 4 Principles of adjuvant systemic therapy.
ER = estrogen receptor.

of features about the cancer, including the size of the invasive component of the cancer, the presence or absence of regional lymph node metastases, the grade of the cancer, and the presence or absence of specific biomarkers associated with prognosis and response to treatment. The three clinically used markers are the estrogen receptor, the progesterone receptor, and HER-2/*neu* protein expression or gene amplification. In making these assessments, it must be recognized that a substantial fraction of women with negative lymph nodes still develop metastatic disease.¹⁵

Treatment entails two major classes of drugs: endocrine drugs, which block the effect of circulating estrogen on breast cancers that express estrogen and progesterone receptors, and systemic cytotoxic chemotherapy. The best available treatments are codified in widely accepted practice guidelines developed and updated annually by the NCCN.¹⁶

Endocrine therapy is effective only for women whose tumors express hormone receptors. This includes premenopausal women and postmenopausal women as they have low levels of circulating estrogens from non-ovarian sources. There are two primary classes of endocrine drugs: SERMs, of which the primary agent used in breast cancer is tamoxifen, and aromatase inhibitors, which block peripheral synthesis of estrogen and are effective only in postmenopausal women.⁷⁸ Recent clinical trials demonstrated that aromatase inhibitors are superior to tamoxifen in preventing the recurrence of breast cancer, with a slightly improved safety profile in postmenopausal women. Aromatase inhibitors are not effective in premenopausal women, for whom tamoxifen remains the drug of choice. These drugs are remarkably safe and effective, with only rare serious side effects.

With only a few exceptions, all women with hormone receptor–positive breast cancers should receive prolonged endocrine therapy. At least 5 years of therapy is warranted.

Ongoing clinical trials are addressing whether prolonged therapy with aromatase inhibitors may be of value.

Women with hormone receptor-positive breast cancers should consider whether to also receive systemic chemotherapy. A large body of evidence from clinical trials shows that survival may be improved by the addition of chemotherapy.^{79,80} However, the magnitude of benefit over the benefit of endocrine therapy alone may be small. For otherwise healthy women who have positive lymph nodes, additional chemotherapy may be strongly considered. For those with negative nodes, the benefit varies according to the characteristics of the cancer. Until recently, many women received chemotherapy for a survival advantage as low as 1%. Recently, genomic profiling of cancers through characterization of the expression of multiple genes has allowed identification of women in this situation with a very high and with a very low risk of distant disease and also has to find which patients benefit from chemotherapy.^{81,82} The most widely used genomic profiling system in breast cancer in 2009 is OncotypeDx. This profiling is validated for use in women with hormone receptor-positive, lymph node-negative invasive breast cancer.

Endocrine therapy is not effective in women with hormone receptor-negative breast cancer. For these women, the only treatment to reduce the risk of distant metastases is cytotoxic chemotherapy.^{79,80} Unless otherwise contraindicated by serious comorbidities, women with cancers over 1 cm and negative hormone receptors should receive chemotherapy.¹⁶ Those with tumors under 1 cm have a lower risk of distant metastases and may derive substantially less benefit from chemotherapy.

Breast cancers that express the HER-2/neu protein have a higher risk of developing distant metastases. However, the monoclonal antibody trastuzumab (Herceptin) directed against HER-2 has proven to be safe and effective when given in combination with chemotherapy. The risk of distant metastatic disease is cut by about half over the benefit of chemotherapy alone when combined with trastuzumab.⁸³

The most difficult situation is when estrogen, progesterone, and HER-2/neu are negative. So-called “triple negative cancers” are more common in younger women, those of African American ancestry, and those with inherited susceptibility. There is active ongoing clinical research to define improved approaches in this setting.

Clinical trials over the last three decades have defined the most effective drugs in breast cancer. Chemotherapy drugs are most effective when used in combination with other drugs. The most effective drugs in breast cancer are the anthracyclines, of which the most widely used agent is doxorubicin (Adriamycin), cyclophosphamide (Cytosan), and the taxanes (paclitaxel and docetaxel). Readers are referred to a large-scale meta-analysis of the value of adjuvant chemotherapy and endocrine therapy and to recent reviews on the subject.^{79,80,84}

Decisions regarding adjuvant systemic therapy are complex for both patients and their physicians. To aid these decisions, there are mathematical models that incorporate relevant prognostic factors and provide individualized risk of distant recurrence and benefit from treatment. The most widely used models are Adjuvant! (www.adjuvantonline.com) and CancerMath.net (<http://cancer.lifemath.net/>).^{85–87}

NEOADJUVANT SYSTEMIC THERAPY AND LOCALLY ADVANCED BREAST CANCER

Locally advanced breast cancer is generally defined as any tumor over 5 cm, involving the skin, or with extensive lymph node involvement [see Figure 5]. In these cases, surgery may be difficult and even standard mastectomy may not be possible. With the advent of chemotherapy in the 1970s, clinical trials investigated the value of systemic treatments, most notably chemotherapy, prior to surgery. These demonstrated that such “neoadjuvant” presurgical therapy with locally advanced breast cancer often reduced the size and extent of the cancer more than 50%, which often allowed standard surgery. Equally interesting was that 15 to 25% had complete disappearance of cancer clinically and half of these women had no viable tumor identified pathologically (pathologic complete response). Neoadjuvant chemotherapy became the accepted standard treatment for locally advanced and inflammatory breast cancer (stage III).

This finding with locally advanced breast cancer led to studies of presurgical chemotherapy with lower-stage cancer.⁸⁸ Large-scale studies, most notably the NSABP B-18 study, demonstrated similar cancer responses with presurgical chemotherapy.⁸⁹ Neoadjuvant therapy did not convey any survival advantage over chemotherapy administered postoperatively. However, women treated with presurgical chemotherapy were more likely to have BCT, and the rate of local recurrence after this treatment was equivalent to that of others receiving BCT. The degree of response to neoadjuvant therapy is itself of significant prognostic importance.^{89–91} Those women who achieve a major response, especially those who achieve a complete pathologic response in the tumor, are more likely to have long-term survival compared with those who do not.⁸⁸ These and other factors have led to an increasing use of neoadjuvant therapy.

Presurgical endocrine therapy may also be of value in select cases.^{92,93} A response to neoadjuvant chemotherapy is most likely among women with high-grade and hormone receptor-negative cancers. Those with endocrine receptor-positive cancers may be somewhat less likely to respond. However, these tumors may also respond to presurgical endocrine therapy, with similar benefits in terms of surgical treatment. With endocrine therapy, the time to maximal tumor response is longer than with chemotherapy; it may take 6 months to achieve maximum tumor response prior to surgery.

It is therefore reasonable to administer neoadjuvant therapy to any woman who would otherwise receive chemotherapy for treatment for breast cancer. In general, neoadjuvant therapy is administered to those with larger T2 cancers (those over three or 4 cm in size) and T3 cancers in an effort to allow breast conservation. In addition, neoadjuvant therapy is the treatment of choice for those with cancer that involves the skin or chest wall (T4), with extensive lymph node involvement clinically, or those who have inflammatory cancer. Regardless of the final surgery type and the degree of tumor response, women with locally advanced breast cancer should receive surgery and radiation.⁹⁴

STAGE IV BREAST CANCER

A small fraction of breast cancers have distant metastases (stage IV) at the time of the initial cancer presentation [see

Figure 5 Schema for treatment of locally advanced breast cancer. BCS = breast-conserving surgery; ER = estrogen receptor; FNA = fine-needle aspiration; SNB = sentinel node biopsy.

Figure 6]. This disease is generally incurable, and treatment is targeted at preventing disease progression for the longest time possible while maintaining high quality of life. It is generally necessary to obtain tissue from the primary tumor to obtain hormone receptor and HER-2/neu information, as well as to biopsy a metastatic site if there is any doubt regarding whether the metastatic deposit is truly a metastasis.

First-line treatment is generally systemic therapy.¹⁶ In the absence of symptomatic or aggressive visceral disease, those with endocrine-sensitive tumors are best treated with oral endocrine therapy. Many may achieve a major response and have long, progression-free intervals with high quality of life without significant treatment-related toxicity. Those with hormone receptor-negative cancers may begin with systemic chemotherapy.

For those diagnosed with metastases before the primary tumor in the breast is removed, there is generally no reason to do surgery. Systemic treatment often provides a major response in the breast and achieves sufficient local control for the duration of the woman's life. For those women fortunate enough to have prolonged survival but in whom the primary

tumor does progress, surgery and/or radiation may be used for local control and preserving quality of life.

There is an interesting literature from population cancer registries suggesting that those women who present with metastatic disease who undergo surgery at the time of diagnosis have longer survival than those who do not have surgery.⁹⁵⁻⁹⁷ However, this finding is most likely a selection bias in that women with a lower burden of disease are more likely to have undergone surgery before the discovery of the metastatic cancer and are therefore more likely to survive longer. There are no controlled clinical trial data to support either argument.

Breast Cancer in Pregnancy

Breast cancer is uncommon in young women but may occur during the childbearing years. Therefore, breast cancer may occur during pregnancy and, in fact, is the second most common cancer associated with pregnancy. Women in this age group are generally not undergoing routine breast cancer screening, and changes in the breast associated with pregnancy can mask the presence of a mass. Therefore, breast

Figure 6 Schema for treatment of women with cancer with distant metastases at presentation (stage IV). ER = estrogen receptor; PR = progesterone receptor.

cancer diagnosis is often delayed in this situation. Women with a suspicious breast mass detected during pregnancy should be evaluated aggressively. Imaging can generally be done with judicious use of mammography, ultrasonography, and biopsy performed as in any woman with a suspicious breast lesion.

The principles of treatment are the same as in any woman with breast cancer.⁹⁸ The only limitations are that chemotherapy cannot be administered during the first trimester and radiation cannot be administered until after delivery. However, neither of these issues limits aggressive treatment of women with breast cancer during pregnancy. Termination of the pregnancy is not necessary, although some women diagnosed early in pregnancy may choose to do so.

Older texts suggested that mastectomy is the preferred treatment in women with breast cancer during pregnancy. However, the same choices are available to women with cancer during pregnancy because the radiation that is administered is generally delayed until after chemotherapy and

therefore is timed to occur after delivery of the child. Therefore, breast conservation can be used safely during pregnancy. Similarly, chemotherapy may be used safely during pregnancy. There are extensive data demonstrating the safety of chemotherapy for both the mother and the fetus. SNB may also be performed during pregnancy using the radioactive tracers. The estimated radiation dose to the fetus is exceedingly low and is considered safe.⁹⁹ The vital dyes isosulfan blue and methylene blue have potential teratogenic effects and are contraindicated during pregnancy.

Women who have breast cancer at a young age or during pregnancy may wish to have additional children. Decades ago, they were advised against this because of concern that hormonal changes associated with pregnancy could promote recurrence. This has been proven incorrect. Women may choose to have children after breast cancer treatment with no additional risk of breast cancer recurrence and death.

Breast Cancer in Men

Breast cancer occurs in men with an incidence less than 1% of that of women. No screening for men is warranted, but a mass in the breast should be fully evaluated. Most masses proved to be gynecomastia. Breast cancer in a younger man may be indicative of inherited susceptibility within that family particularly related to *BRCA2*. Careful family history and counseling regarding this risk should be provided.

The treatment of breast cancer in men follows the same principles as in women.^{100,101}

Surgery is generally mastectomy because of the tumor is directly under the nipple complex. Wide margins should be obtained. Radiation may be administered if the tumor is larger or involves the skin and/or chest wall. SNB and axillary lymph node dissection should be performed using the same indications as in women. Men should also receive adjuvant systemic therapy using the same criteria as women. Most are hormone receptor positive, and endocrine therapy is effective.

Follow-up after Breast Cancer Treatment

Patients who have been treated for invasive breast cancer are at risk for developing distant metastases, local recurrence, and a contralateral or ipsilateral new breast cancer. Most recurrences occur within the first 5 to 10 years, with the peak at 4 to 6 years. Occasionally, women develop distant metastases many years later.

Women with breast cancer often assume that careful screening is warranted to allow early detection of metastases on the assumption that early detection will provide a better chance of a successful outcome. Unfortunately, there is no such entity as early metastatic cancer. Once breast cancer metastases are established to the extent that they are detectable, there is no therapy that is curative, and treatment is largely palliative, as discussed above related to stage IV breast cancer. Because of this, extensive testing for metastatic disease on a periodic basis does not provide any advantage to a woman with breast cancer.¹⁰² This question has actually been tested in randomized clinical trials of extensive testing versus simple follow-up for local recurrence only combined with evaluation of any symptoms suggestive of metastatic disease.

These studies showed no survival advantage despite detection of metastatic disease, and those recurred an average of 3 months earlier in the screened group.

Screening women for evidence of local recurrence with both invasive and in situ cancer may be of value. This should include mammography of the ipsilateral breast in women treated with breast conservation, contralateral mammography for all women, and a careful history and physical examination. Mammography should be done annually, with the history and physical examination done every 6 to 12 months. The role of breast MRI in breast cancer follow-up is unclear. Women should maintain a primary care provider to be sure that other regular medical care is provided.

CANCER SURVIVORSHIP

In addition to covering medical issues in cancer follow-up, surgeons should provide ongoing resources to help women adjust to the cancer diagnosis, deal with psychological issues, address cancer genetic and family concerns, and identify other long-term sequelae of cancer.¹⁰³ Patients should be provided with a written “care plan” for their ongoing care and should be encouraged to seek individual counseling and participate in support groups as they see the need and to gain the value of engagement in the vast array of support and advocacy activities available in most communities.¹⁰⁴

2 SOFT TISSUE INFECTION

Mark A. Malangoni, M.D., F.A.C.S., and Christopher R. McHenry, M.D., F.A.C.S.

Approach to the Patient with Soft Tissue Infection

Soft tissue infections are a diverse group of diseases that involve the skin and underlying subcutaneous tissue, fascia, or muscle. Such infections may be localized to a small area or may involve a large portion of the body. They may affect any part of the body, though the lower extremities, the perineum, and the abdominal wall are the most common sites of involvement. Some soft tissue infections are relatively harmless if treated promptly and adequately; others can be life-threatening even when appropriately treated. The symptoms and signs range from subtle or nonspecific indicators (e.g., pain, localized tenderness, and edema without fever) to obvious features (e.g., necrosis, blistering, and crepitus associated with systemic toxicity).

Soft tissue infections were first defined as such more than a century ago. In 1883, Fournier described a gangrenous infection of the scrotum that continues to be associated with his name.¹ In 1924, Meleney documented the pathogenic role of streptococci in soft tissue infection.² Shortly thereafter, Brewer and Meleney described progressive polymicrobial postoperative infection of the muscular fascia with necrosis³ (though the term necrotizing fasciitis was not introduced until more than 25 years later⁴). The association between toxic-shock syndrome and streptococcal soft tissue infection was delineated as this disease reemerged in the 1980s.⁵

Various classification systems and eponyms are used to describe specific forms of soft tissue infection [see Discussion, Etiology and Classification of Soft Tissue Infection, below]. In our view, however, it is more important to develop a common approach to the diagnosis and treatment of these conditions than to refine the minor details of classification. For therapeutic purposes, the primary consideration is to distinguish between necrotizing soft tissue infections and nonnecrotizing infections. Nonnecrotizing soft tissue infections involve one or both of the superficial layers of the skin (epidermis and dermis) and the subcutaneous tissue, and they usually respond to antibiotic therapy alone. Necrotizing soft tissue infections may involve not only the skin, the subcutaneous tissue, and the superficial fascia but also the deep fascia and muscle, and they must be treated with urgent surgical debridement. At times, it is difficult to distinguish between these two categories of infection, especially when obvious clinical signs of necrotizing soft tissue infection are absent.

In this chapter, we review diagnosis and management of the main soft tissue infections seen by surgeons, including both superficial infections (e.g., pyoderma, animal and human bites, and cellulitis) and necrotizing infections involving superficial and deep tissues [see Table 1].

Clinical Evaluation

The diagnosis of soft tissue infection is usually made on the basis of the history and the physical examination. Patients typically seek medical attention because of pain, tenderness, and erythema of recent onset. They should be asked about environmental

factors that may have disrupted the normal skin barrier [see Table 2], as well as about any host factors that may increase their susceptibility to infection and limit their ability to contain it. It is particularly important that they be questioned about specific clinical scenarios associated with unusual pathogens, such as an animal bite (associated with *Pasteurella multocida*), a human bite (*Eikenella corrodens*), chronic skin diseases (*Staphylococcus aureus*), saltwater exposure or ingestion of raw seafood (*Vibrio vulnificus*), and brackish or freshwater exposure (*Aeromonas hydrophila*).

Physical examination usually reveals erythema, tenderness, and induration. Vesicular lesions and honey-colored crusted plaques are seen in patients with impetigo. Intense, sharply demarcated erythema is characteristic of erysipelas. A tender, swollen erythematous papule, often containing a visible hair shaft, is indicative of folliculitis. A single painful, tender, indurated, erythematous skin nodule suggests a furuncle, and the presence of multiple inflammatory nodules with sinus tracts is consistent with a carbuncle. Cellulitis in association with a decubitus ulcer or an ischemic leg ulcer frequently signals a polymicrobial infection with gram-negative organisms. An erythematous linear streak, characteristic of lymphangitis, usually indicates a superficial infection secondary to *Streptococcus pyogenes*; associated lymphadenopathy may be present as well.

Patients with necrotizing soft tissue infections often complain of severe pain that is out of proportion to their physical findings. Compared with patients who have nonnecrotizing infections, they are more likely to have fever, bullae, or blebs [see Figure 1]; signs of systemic toxicity; hyponatremia; and leukocytosis with a shift in immature forms. Physical findings characteristic of a necrotizing infection include tenderness beyond the area of erythema, crepitus, cutaneous anesthesia, and cellulitis that is refractory to antibiotic therapy.⁶ Tenderness beyond the borders of the erythematous

area is an especially important clinical clue that develops as the infection in the deeper cutaneous layers undermines the skin. Early in the course of a necrotizing soft tissue infection, skin changes may be minimal despite extensive necrosis of the deeper cutaneous layers. Bullae, blebs, cutaneous anesthesia, and skin necrosis occur as a result of thrombosis of the nutrient vessels and destruction of the cutaneous nerves of the skin, which typically occur late in the course of infection.

Clinicians should be mindful of certain diagnostic barriers that may delay recognition and treatment of necrotizing soft tissue infections.⁷ In particular, these infections have a variable clinical presentation. Although most patients present with an acute, rapidly progressive illness and signs of systemic toxicity, a subset of patients may present with a more indolent, slowly progressive infection. Patients with postoperative necrotizing infections often have a more indolent course. Moreover, in the early stages, underlying necrosis may be masked by normal-appearing overlying skin. As many as 20% of necrotizing soft tissue infections are primary (idiopathic) and occur in previously healthy patients who have no predisposing factors and no known portal of entry for bacterial inoculation. Finally, crepitus is noted in only 30% of patients with necrotizing soft tissue infections. Overall, fewer than 40% of patients exhibit the classic symptoms and signs described.^{8,9} Accordingly, it is imperative to maintain a high index of suspicion for this disease in the appropriate setting.

Investigative Studies

Diagnostic studies have a low yield in patients with superficial soft tissue infections. They are rarely necessary and are used only in specific clinical circumstances. Either needle aspiration at the advancing edge of erythema with Gram staining and culture or full-thickness skin biopsy and culture may be helpful when cellulitis is refractory to antibiotic therapy or when an unusual causative organism is suspected. Because of their low yield, blood cultures are obtained only in patients with signs of systemic toxicity, those with buccal or periorbital cellulitis, and those with infection suspected of being secondary to saltwater or freshwater exposure; these clinical situations are associated with a higher likelihood of a positive culture.

When the characteristic clinical features of necrotizing soft tissue infection are absent, diagnosis may be difficult. In this setting, laboratory and imaging studies become important [see Figure 2]. In one study, logistic regression analysis showed that an elevated white blood cell (WBC) count ($\geq 15,400/\text{mm}^3$) and hyponatremia (serum sodium level lower than 135 mmol/L) at the time of hospital admission were highly sensitive for the presence of a necrotizing soft tissue infection; however, the positive predictive

value of these findings was only 26%.¹⁰ The absence of these findings in a patient without obvious clinical signs of a necrotizing soft tissue infection had a negative predictive value of 99%. A normal serum creatine kinase (CK) level rules out muscle necrosis.

In a 2004 report, one group of investigators described the development and application of the Laboratory Risk Indicator for Necrotizing fasciitis (LRINEC) score.¹¹ This scoring system assigns points for abnormalities in six independent variables: serum C-reactive protein level ($> 150 \text{ mg/L}$), WBC count ($> 15,000/\text{mm}^3$), hemoglobin level ($< 13.5 \text{ g/dl}$), serum sodium level ($< 135 \text{ mmol/L}$), serum creatinine level ($> 1.6 \text{ mg/dl}$), and serum glucose level ($> 180 \text{ mg/dl}$). With a score of 8 or higher, there is a 75% risk of a necrotizing soft tissue infection. The authors of the report recommended that the LRINEC score be used to determine which patients require further diagnostic testing, given that the negative predictive value of this screening tool was 96%.

A plain x-ray of the involved area demonstrates soft tissue gas in only 15% to 30% of patients with necrotizing infections [see Figure 3].⁶ Computed tomography is more sensitive in identifying soft tissue gas, but other CT findings are seldom diagnostic.

Magnetic resonance imaging is currently the preferred imaging study for documenting deep necrotizing infections [see Figure 4]. The presence of soft tissue gas on MRI is diagnostic of a necrotizing soft tissue infection. T_2 -weighted images demonstrate thickening and increased signal intensity of the deep fascial planes.^{12,13} Increased signal intensity in the subcutaneous tissue and edema of the adjacent muscle are also frequently present. High signal intensity on T_2 -weighted images and tissue enhancement after gadolinium administration are indicative of inflamed tissue and may also occur with certain nonnecrotizing soft tissue conditions (e.g., exertional muscle injury, lymphedema, dermatomyositis, polymyositis, eosinophilic fasciitis, and neoplastic disease).¹³⁻¹⁷ Low or absent signal intensity on gadolinium-enhanced T_1 -weighted images is indicative of necrosis, a finding that is more specific for a necrotizing soft tissue infection.¹⁸⁻²⁰ The reported sensitivity of MRI for diagnosis of necrotizing soft tissue infection ranges from 89% to 100%, and its specificity ranges from 46% to 86%.^{18,20}

A prospective study from 2000 evaluated the use of MRI to differentiate necrotizing from nonnecrotizing soft tissue infection in nine patients.²⁰ The absence of gadolinium enhancement on T_1 -weighted images was indicative of fascial necrosis in all six patients

Figure 1 Lower-extremity necrotizing fasciitis is characterized by bullae, blebs, and discolored skin.

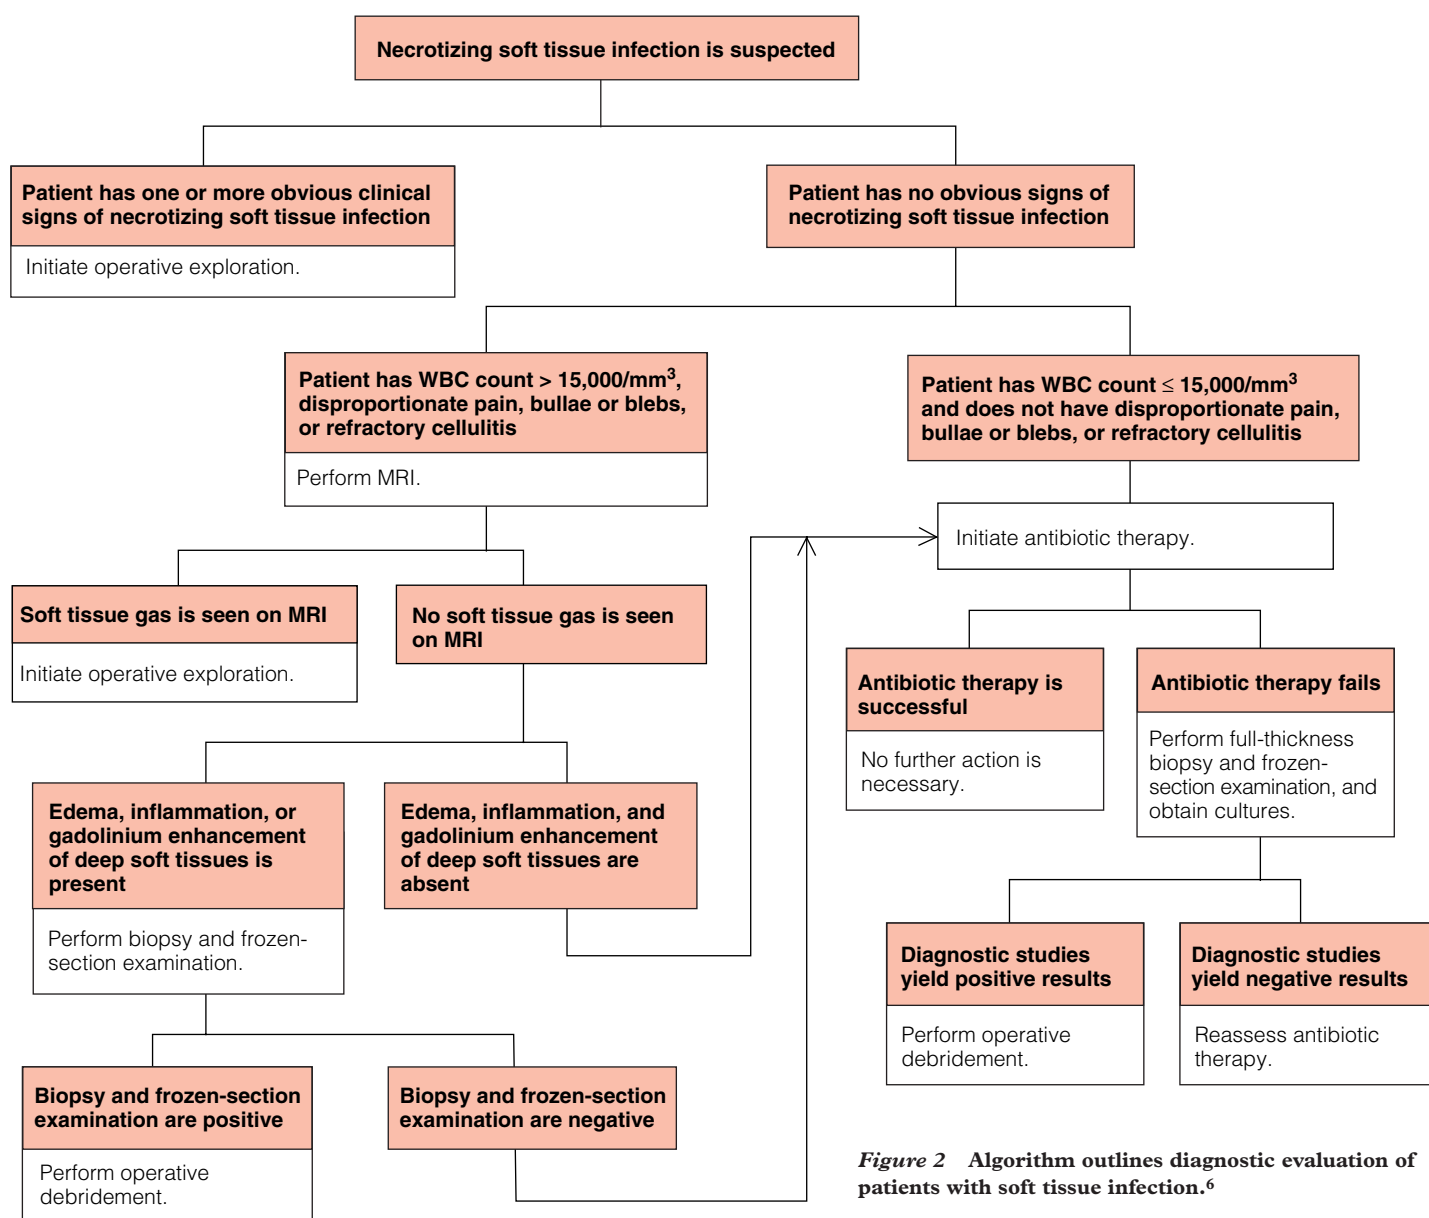

Figure 2 Algorithm outlines diagnostic evaluation of patients with soft tissue infection.⁶

who underwent operative debridement.²⁰ Operation was avoided in two patients who showed no evidence of necrosis on MRI. A third patient without MRI evidence of necrosis underwent operative exploration because of a high degree of clinical suspicion and was diagnosed as having nonnecrotizing cellulitis. In a prospective study from 1998, the investigators successfully employed MRI to differentiate necrotizing from nonnecrotizing infections in 16 of 17 patients (11 of 11 patients with necrotizing fasciitis and five of six patients with nonnecrotizing cellulites).¹⁹

The finding of soft tissue gas on diagnostic imaging warrants immediate operative exploration and debridement. Because of the high sensitivity of MRI, necrotizing infection can be excluded when no involvement of the superficial fascia, subcutaneous tissue, or the deeper cutaneous layers is demonstrated. However, the inflammatory changes seen on MRI when necrotizing soft tissue infection is present may also be seen in patients with nonnecrotizing infections, as well as in those with other inflammatory conditions affecting the deep soft tissues. Because of the relatively low specificity of this study, biopsy of the deeper cutaneous layers, with frozen-section examination and culture, may be needed to diag-

nose or rule out soft tissue infection [see Figure 2]. This procedure may be performed at the bedside with local anesthesia. The observation of necrotic or infected tissue through the biopsy incision indicates that immediate debridement is needed.

General Management of Nonnecrotizing and Necrotizing Soft Tissue Infection

NONNECROTIZING INFECTION

Antibiotic therapy is the cornerstone of treatment for patients with nonnecrotizing infections. Such patients usually require antibiotics that are effective against group A streptococci or *S. aureus*. The prevalence of community-acquired methicillin-resistant *S. aureus* (MRSA) strains has increased significantly. These strains now outnumber methicillin-sensitive strains by a two-to-one margin.²¹ This development has necessitated a change in the empirical treatment of these infections. Topical, oral, or intravenous preparations may be employed, depending on the nature and severity of the disease process [see Management of Specific

Figure 3 Upper-extremity x-ray of a patient with necrotizing soft tissue infection demonstrates soft tissue gas outlining the muscles.

Figure 4 Lower-extremity MRI of a patient with necrotizing fasciitis of the left leg demonstrates inflammatory changes typical of necrosis.

Soft Tissue Infections, *below*]. If polymicrobial infection is suspected, broad-spectrum antimicrobial agents should be given, either alone or in combination.

NECROTIZING INFECTION

Management of necrotizing soft tissue infections is predicated on early recognition of symptoms and signs and on emergency operative debridement. Once the diagnosis of necrotizing soft tissue infection is established, patient survival and limb salvage are best achieved by means of prompt operation; precise identification of the causative bacteria and correct assignment of the patient to a specific clinical syndrome are unnecessary. The delay between hospital admission and initial debridement is the most critical factor influencing morbidity and mortality: a number of reports have demonstrated a strong correlation between survival and the interval between onset of symptoms and initial operation.^{9,22-24}

The components of treatment of necrotizing soft tissue infection are (1) resuscitation and correction of fluid and electrolyte disorders, (2) physiologic support, (3) broad-spectrum antimicrobial therapy, (4) urgent and thorough debridement of necrotic tissue, and (5) supportive care [see *Figure 5*].

Nonoperative Measures

Patients with necrotizing soft tissue infections frequently present with tachycardia and hypotension, reflecting depleted intravascular volume and possible septic shock. Such patients often exhibit extensive extracellular fluid sequestration within the affected area, as well as more generalized sequestration resulting from sepsis. A balanced isotonic electrolyte solution, such as lactated Ringer solution (or 0.9% normal saline, for patients with renal dysfunction), is administered to replace these fluid deficits. The adequacy of intravascular volume repletion is often assessed by monitoring vital signs and urinary output; however, it sometimes proves necessary to use a central venous catheter to monitor central venous or pulmonary arterial pressure in patients with associated myocardial dysfunction, septic shock, chronic pulmonary disease, renal insufficiency, or other severe chronic illnesses.

Hyponatremia is usually corrected by infusing isotonic fluids. Hypocalcemia, which can result from calcium precipitation in patients with extensive fat necrosis, is usually corrected by administering I.V. calcium gluconate. Hyperglycemia is corrected with insulin, given either via subcutaneous injection or, for patients with more severe abnormalities, via I.V. infusion. Lactic acidosis generally responds to fluid administration. Renal function is assessed by measuring blood urea nitrogen (BUN) and serum creatinine concentrations. CK levels should be monitored and a qualitative evaluation of urine myoglobin done if muscle necrosis is suspected or renal failure is present. Myoglobinuria and elevated CK levels are

Figure 5 Algorithm outlines treatment of necrotizing soft tissue infection.

Table 3 I.V. Antibiotic Dosages for Adult Patients with Necrotizing Soft Tissue Infection and Normal Renal Function

Single agents	Ampicillin-sulbactam	3 g q. 6 hr
	Imipenem-cilastatin	500–750 mg q. 6 hr
	Meropenem	1–2 g q. 8 hr
	Piperacillin-tazobactam	3.375 g q. 6 hr
	Ticarcillin-clavulanate	3.1 g q. 6 hr
Agents used in combination regimens	Aerobic/facultative coverage	
	Ampicillin	2 g q. 6 hr
	Cefotaxime	1–2 g q. 8 hr
	Ceftazidime	1 g q. 8 hr
	Cefuroxime	1.5 g q. 8 hr
	Ciprofloxacin	400 mg q. 12 hr
	Daptomycin	4 mg/kg q. 24 hr
	Gentamicin	1.7 mg/kg q. 8 hr or 5.1 mg/kg q. 24 hr
	Linezolid	600 mg q. 12 hr
	Moxifloxacin	400 mg q. 24 hr
	Tigecycline	100 mg initially; then 50 mg q. 12 hr
	Vancomycin	1 g q. 12 hr
	Anaerobic coverage	
	Clindamycin	600–900 mg q. 8 hr
	Metronidazole	500 mg q. 6 hr

suggestive of myonecrosis. Anemia is treated with packed red blood cell transfusions.

Patients whose hypotension does not resolve with appropriate intravascular fluid resuscitation often experience septic shock. In these circumstances, low dosages of I.V. dopamine (5 to 10 µg/kg/min), vasopressin (0.1 to 0.4 IU/min), or norepinephrine (0.02 to 0.08 µg/kg/min) are useful for raising blood pressure and improving myocardial function.

Patients with traumatic wounds or other contaminated sites should receive tetanus toxoid or human tetanus immunoglobulin, depending on their immunization status.

Hyperbaric oxygen has been advocated as adjunctive therapy for extensive necrotizing infections, particularly those caused by clostridia.²⁵ The beneficial properties of hyperbaric oxygen include inhibition of bacterial exotoxin production [see Discussion,

Pathogenesis of Soft Tissue Infections, *below*], improved leukocyte function, and attainment of tissue oxygen levels that are bactericidal for *Clostridium perfringens* and bacteriostatic for other anaerobic bacteria. Hyperbaric oxygen does not, however, neutralize exotoxin that has already been released.²⁵ At present, except for some data from retrospective studies, there is little evidence supporting the benefits of hyperbaric oxygen therapy. Such therapy has not been demonstrated to improve survival or to bring about earlier resolution of necrotizing soft tissue infection, and it has been associated with barotrauma, pneumothorax, and oxygen toxicity. Accordingly, we believe that operative debridement should not be delayed to accommodate hyperbaric oxygen therapy and that such therapy should not be considered a substitute for complete debridement of infected nonviable tissues.

I.V. antimicrobial therapy is indicated in all patients with necrotizing soft tissue infections [see Table 3]. Such therapy is important, but it is not a substitute for prompt and adequate operative debridement. Necrotizing soft tissue infections are most often caused by a mixed polymicrobial bacterial flora [see Table 4]. Approximately 25% to 30% of necrotizing soft tissue infections are monomicrobial. Although *S. pyogenes* is the bacterium most frequently involved, the microbiology of the infections often cannot be accurately predicted before final identification of organisms on culture. Thus, the empirical antibiotic regimen chosen should be effective against a diverse group of potential pathogens.²⁶ In addition, because these patients have a high incidence of associated nosocomial infections and even of metastatic infections, it is important to ensure that the dosage is high enough to achieve adequate serum concentrations.^{9,23} Once the results of intraoperative culture and antimicrobial sensitivity testing become available, antibiotic therapy is adjusted accordingly. This adjustment can be challenging, in that all of the pathogens identified must be treated.

I.V. antimicrobial therapy is continued until operative debridement is complete, there is no further evidence of infection in the involved tissues, and signs of systemic toxicity have resolved. Topical antiseptic agents (e.g., Dakin solution and Burrow solution) may help control infection that progresses despite adequate debridement and I.V. antibiotics. Topical application of mycostatin powder may help control progressive fungal infection. When patients are able to resume oral intake, they can often be switched from I.V. to oral antimicrobial therapy. Antimicrobial therapy should not, however, be prolonged merely because oral agents are available.

Operative Treatment

The most critical factors for reducing mortality from necrotizing soft tissue infections are early recognition and urgent operative debridement.^{9,22,24,27} The extent of debridement depends on intraoperative findings and cannot be accurately predicted before operation. Operative intervention helps limit tissue damage by removing necrotic tissue, which serves as a nidus for infection.

Thorough exploration is necessary to confirm the diagnosis of necrotizing soft tissue infection and determine the degree of involvement. Aggressive, widespread debridement of all apparent necrotic, infected tissue is essential; antibiotics will not penetrate dead tissues. The underlying necrosis of subcutaneous tissues, fascia, and muscle typically extends beyond the obvious limits of cutaneous involvement. Operative debridement should therefore be continued until viable tissue is reached. In most instances, the involved tissues are easily separated from their surrounding structures. The presence of “dishwater pus” and noncontracting muscle are additional indicators of necrotizing infection. The presence of arterial bleeding generally indicates that tissues are viable; in the

Table 4 Organisms Causing Necrotizing Soft Tissue Infection

Aerobes	Gram-positive

	<i>Serratia</i> species
	<i>Acinetobacter calcoaceticus</i>
	<i>Vibrio vulnificus</i>
Anaerobes	<i>Bacteroides</i> species
	<i>Clostridium</i> species
	<i>Peptostreptococcus</i> species

absence of arterial bleeding, tissues are nonviable even if venous bleeding is present. With deep necrotizing infections, debridement of the necrotic fascia and muscle may create large skin flaps that are poorly perfused. It is best to preserve as much viable skin and subcutaneous tissue as possible because these tissues can be essential for later coverage of the wound. Nonviable skin, however, should be resected.

Wound drainage or exudate should be submitted for Gram staining, as well as for aerobic, anaerobic, and fungal cultures and antimicrobial sensitivity testing. Fasciotomy is rarely required. The presence of subcutaneous gas extending beyond areas of nonviable tissue does not necessitate debridement if the surrounding tissues are viable. It is sometimes helpful to perform an exploratory incision over an area beyond the limits of debridement when it is uncertain whether necrosis is undermining viable skin. If no necrotizing infection is found, the incision may be closed primarily.

Reexploration should be routinely performed within 24 to 48 hours to ensure that all necrotic tissue has been debrided. Debridement is repeated as necessary until the infection is controlled. If repeated debridement does not control infection, if there are persistent, fulminant infections of the extremities, or if an extremity remains nonfunctional after debridement has been completed, amputation can be lifesaving. Amputation is most often required for patients with clostridial myonecrosis and for diabetic patients with necrotizing infections.²⁴ In two large series of patients with necrotizing soft tissue infections, the incidence of amputation was approximately 15% to 25%.^{9,22}

Patients with necrotizing soft tissue infections involving the perineum and perirectal areas may need a diverting colostomy to prevent tissue contamination resulting from defecation and to control local infection. Overall, this measure is required in fewer than 25% of cases.⁹

After debridement, the exposed areas should be treated with 0.9% normal saline wet-to-dry dressings. Once the initial infection has been controlled and debridement is no longer necessary, dressing changes can often be performed at the bedside after sufficient analgesics have been given to achieve adequate pain management. Patient-controlled analgesia is frequently useful early in the course of treatment. Propofol or ketamine can be given in the intensive care unit to facilitate pain control during dressing changes.

Early enteral or parenteral nutritional support should be instituted to optimize recovery. Nutritional support should begin once resuscitation is complete, the infection is adequately controlled, and the signs of sepsis have resolved. Because it frequently proves necessary to return the patient to the operating room, enteral feeding tubes should be placed beyond the pylorus so that enteral nutrition can be provided without interruption. Alternatively, parenteral nutrition may be employed.

Once the localized infection is under control and the patient is recovering, the exposed soft tissues should be covered. This is most commonly done with split-thickness skin grafting, though other reconstructive procedures (e.g., rotational flaps) [see 3:7 *Surface Reconstruction Procedures*] can be effective in this setting as well. Vacuum-assisted closure devices can reduce the exposed surface area and lessen the need for skin graft coverage. Exposed tendons, nerves, or bone often should be covered with full-thickness skin to prevent desiccation and preserve limb function. Premature closure of highly contaminated or persistently infected sites usually fails and leads to recurrence of infection and a greater likelihood of death.

When the abdominal or chest wall has been excised to control infection, reconstruction is necessary. Prosthetic mesh is useful for restoring continuity of the abdomen or the chest wall, and overlying moist dressings can help prevent desiccation of underlying vis-

cera. Some have advocated using biologic materials or absorbable mesh for restoration of abdominal wall continuity; however, we prefer to use permanent mesh in most circumstances, especially when omentum is available for interposition between the mesh and the small intestine.⁹

Mortality from necrotizing soft tissue infection ranges from 21% to 29%.^{9,22,24,27,28} Risk factors for mortality include age greater than 60 years, the presence of associated chronic illnesses, a relatively high percentage of total body surface area involved, and, most important, delays in recognition and treatment.^{9,22,24} Patients with truncal involvement or positive blood cultures also have a higher mortality.^{22,28}

Management of Specific Soft Tissue Infections

Normal skin functions as a protective barrier that prevents microorganisms from causing soft tissue infection. The skin is made up of two layers, the epidermis and the dermis [see Figure 6]. The epidermis, the outer avascular epithelial layer, functions as a permeability barrier for the rest of the body. The dermis, the inner layer, contains blood vessels, lymphatic vessels, sweat and sebaceous glands, and hair follicles. The subcutaneous tissue separates the skin from the deep fascia, muscle, and bone. Typically, soft tissue infections result from disruption of the skin by some exogenous factor; less commonly, they result from extension of a subjacent infection or hematogenous spread from a distant site of infection.

SUPERFICIAL INFECTIONS

Superficial infections constitute the majority of soft tissue infections. They primarily involve the epidermis or dermis (pyoderma)

Figure 6 Depicted is the normal anatomy of the skin and the deeper cutaneous layers.⁶

Table 5 Topical and Oral Antibiotic Agents Used for Superficial Soft Tissue Infections*

Mupirocin ointment (2%), applied to affected area t.i.d.†
Erythromycin ointment (2%), applied to affected area b.i.d.†
Clindamycin gel or lotion (1%), applied to affected area b.i.d.†
Gentamicin cream or ointment (0.1%), applied to affected area t.i.d. or q.i.d.
Penicillin V, 250–500 mg q.i.d. (pediatric: 25–50 mg/kg in divided doses q.i.d.)
Amoxicillin, 250–500 mg t.i.d. (pediatric: 20–30 mg/kg/day p.o. in divided doses t.i.d.)
Dicloxacillin, 250–500 mg q.i.d. (pediatric: 12.5–25.0 mg/kg/day in divided doses q.i.d.)
Cephalexin, 250–500 mg q.i.d. (pediatric: 25–100 mg/kg/day in divided doses q.i.d.)
Cefadroxil, 500–1,000 mg b.i.d. (pediatric: 30 mg/kg/day in divided doses b.i.d.)
Erythromycin, 250–500 mg q. 6 hr (pediatric: erythromycin ethyl succinate, 40 mg/kg in divided doses q.i.d.)
Clindamycin, 150–450 mg q.i.d. (pediatric: 20 mg/kg/day in divided doses t.i.d. or q.i.d.)
Trimethoprim-sulfamethoxazole, 160/800 mg b.i.d.
Amoxicillin-clavulanate, 500 mg t.i.d. (pediatric: 40 mg/kg/day in divided doses t.i.d.)
Ciprofloxacin, 500 mg p.o., b.i.d.

*All dosages are for patients with normal renal function.

†Adult dosage and pediatric dosage are the same.

or the subcutaneous tissue (cellulitis) and secondarily occur in skin damaged by animal or human bites. Nonnecrotizing superficial soft tissue infections are principally treated with antibiotics. Necrosis is rare but may develop in superficial infections that are inadequately treated or neglected.

Pyoderma

Pyoderma is a general term referring to a bacterial infection of the skin. It may be divided into several subcategories, including impetigo, erysipelas, folliculitis, and furuncles and carbuncles.

Impetigo Impetigo is a highly contagious bacterial infection that is confined to the epidermis and that usually involves the face or the extremities. It is most common in infants and preschool children and is seen more frequently in patients with preexisting skin conditions (e.g., eczema, atopic dermatitis, varicella infection, angular cheilitis, and scabies). Warm and humid weather, crowded living conditions, and poor hygiene can all contribute to the development of impetigo.²⁹ The dominant pathogen is *S. aureus*, which causes either a bullous or a nonbullous form of the disease; a less common pathogen is *S. pyogenes*, which causes a nonbullous form.³⁰

Impetigo usually occurs in areas of skin breakdown, though *S. aureus* may give rise to de novo infection in normal skin. Bullous impetigo is manifested by numerous blisters or bullae that rapidly become pustules, then rupture within 1 to 2 days to form a thick, honey-colored, crusted plaque that remains for days to weeks. Nonbullous impetigo is characterized by erythema and tiny, less prominent vesicles that progress to crusted erosions in the skin. The skin lesions are intensely pruritic, and local spread may occur as a result of scratching and release of infected fluid from the blisters, bullae, or vesicles. Associated regional lymphadenopathy is common. Glomerulonephritis may complicate streptococcal-induced impetigo.^{30,31}

The diagnosis is established by Gram stain and culture of the vesicular fluid or the crusted plaque. The skin lesions usually resolve spontaneously within 2 to 3 weeks.³¹ Antibiotic therapy accelerates the resolution of these lesions. Mupirocin ointment (2%) is applied topically three times a day until the lesions clear. This agent possesses excellent in vitro activity against both staphylococci and streptococci and achieves high rates of cure in patients with localized disease. Erythromycin and clindamycin ointments are acceptable alternatives [see Table 5]. For patients who have disseminated impetigo or impetigo of the scalp or mouth and those in whom topical therapy fails, an oral antibiotic (e.g., dicloxacillin, cephalexin, cefadroxil, erythromycin, or clindamycin) may be used [see Table 5]. A 7-day course of oral antibiotic therapy is usually sufficient.³¹

Erysipelas Erysipelas is an acute bacterial infection that principally involves the dermis. It is almost invariably caused by *S. pyogenes*. Most cases are preceded by influenzalike symptoms. Infection extends through the dermal lymphatic vessels and is typically manifested by a tender, pruritic, intensely erythematous, sharply demarcated, and raised plaque. Patients complain of pain, often in conjunction with high fever, increased skin warmth, and leukocytosis. Lymphangitis and lymphadenopathy are sometimes present as well. The leg is the most common site of involvement, but erysipelas may also occur on the face, the arms, and the upper thighs.

The factors predisposing to the development of erysipelas of the extremity include local conditions such as tinea pedis (athlete's foot), leg ulcers, and venous stasis dermatitis.³² Erysipelas tends to be more common in the presence of associated conditions such as lymphedema, diabetes mellitus, alcoholism, immunocompromise, and obesity,^{30,32} and it is more likely to recur in patients with these associated diseases and in those whose underlying skin conditions are inadequately treated. Erysipelas recurs in 10% of patients within 6 months of their first episode and in 30% within 3 years.³²

The standard antibiotic treatment for uncomplicated erysipelas is penicillin, which is effective in at least 80% of cases. Oral and intravenous antibiotic regimens are equally efficacious. Amoxicillin appears to work as well as penicillin. Patients with erysipelas of the lower extremity should be placed on bed rest, and the involved leg should be elevated to reduce edema and pain. Once the patient is able to resume normal activities, he or she should be fitted with elastic stockings, which help reduce the occurrence of edema and lower the risk of lymphedema. For patients with tinea pedis, a topical antifungal agent is used to treat the infection and prevent recurrence.

Folliculitis Folliculitis is an infection of the hair follicle that is typically caused by *S. aureus*. It is characterized by a painful, tender, erythematous papule with a central pustule. A shaft of hair is often seen in the center of the pustule. Shaving, plucking, waxing, heat and humidity, the use of corticosteroids or antibiotics, immunosuppression, and occlusion of the skin by clothing, adhesives, or plastics may predispose to folliculitis.²⁹ Single or multiple lesions may occur in the skin of any hair-bearing area. If the pustule ruptures, superficial erosion often ensues. Infection that principally involves the deeper part of the hair follicle is characterized by a tender, swollen papule without an associated pustule at the skin surface.

In rare cases, folliculitis is caused by pathogens other than *S. aureus*, such as *Pseudomonas aeruginosa*, *Klebsiella* species, *Enterobacter* species, *Proteus* species, yeasts, and fungi. *Pseudomonas* folliculitis usually results from exposure to inadequately chlorinated

ed water in swimming pools, hot tubs, or whirlpools. Patients with this infection have multiple papular or pustular lesions on the back, the buttocks, and the extremities, along with fever and malaise appearing 6 hours to 3 days after exposure.^{31,33} Organisms may be cultured either from the pustules or from the infected water. *Klebsiella*, *Enterobacter*, and *Proteus* species can cause folliculitis in patients receiving long-term antibiotic therapy for acne vulgaris.³⁰ Yeast folliculitis and fungal folliculitis tend to occur in immunocompromised patients.³⁰

In most patients, folliculitis resolves spontaneously within 7 to 10 days.³¹ Topical therapy with clindamycin, erythromycin, or mupirocin ointments or benzoyl peroxide in combination with warm soaks may accelerate resolution [see Table 5]. Isotretinoin can be used to treat gram-negative folliculitis. Gentamicin cream may be helpful in drying out the pustular lesions in patients with *Pseudomonas* folliculitis.

In patients with refractory or disseminated follicular infections, oral antibiotic therapy is indicated. When *S. aureus* is considered the most likely pathogen, trimethoprim-sulfamethoxazole, a tetracycline, or clindamycin should be given, in view of the high prevalence of MRSA^{21,34}; an oral quinolone is indicated for the treatment of gram-negative folliculitis [see Table 5]. Elimination of predisposing factors is important for reducing the likelihood of recurrence.

Furuncles and carbuncles Furuncles and carbuncles are deeper infections of the hair follicle that extend beyond the follicle to involve the subcutaneous tissue. For both, *S. aureus* is the usual causative organism.

A furuncle, or boil, is a small abscess, manifested as a firm, tender, erythematous nodule that tends to occur in skin areas exposed to friction (e.g., the inner thighs and the axilla). Furuncles also may occur on the face, the neck, the upper back, and the buttocks. Possible predisposing factors include increased friction and perspiration (as seen in obese individuals or athletes), corticosteroid use, diabetes mellitus, and inherited or acquired defects in neutrophil function.^{29,31}

Initial treatment consists of applying warm compresses to help promote drainage and administering an oral antimicrobial agent that is effective against *S. aureus* (e.g., dicloxacillin, cephalixin, cefadroxil, erythromycin, or clindamycin for infections presumed to be caused by methicillin-sensitive strains; trimethoprim-sulfamethoxazole, a tetracycline, or clindamycin for suspected MRSA infections) [see Table 5]. With time, the furuncle becomes fluctuant, and the pus coalesces at the skin surface. An incision-and-drainage procedure is necessary when these lesions do not drain spontaneously. This procedure should be performed with local anesthesia, and care should be taken to open the abscess cavity completely. Lesions that have drained spontaneously should be examined to confirm that the cavity has been opened sufficiently. Failure to drain these lesions adequately may result in recurrence, as well as in progression to a more serious infection.

A carbuncle is a deep cutaneous infection involving multiple hair follicles that is characterized by destruction of fibrous tissue septa and consequent formation of a series of interconnected abscesses. It is typically manifested by a painful, red, tender, indurated area of skin with multiple sinus tracts. Systemic manifestations (e.g., fever and malaise) are common. Carbuncles occur most frequently on the nape of the neck, the upper part of the back, or the posterior thigh. The thickness of the overlying skin in these areas leads to lateral extension of the infection and loculation. Patients commonly present with relatively large skin lesions that represent a confluence of inflammatory nodules. These lesions are associated with chronic drainage, sinus tracts, and scarring.

Table 6 Risk Factors for Soft Tissue Infection Complicating Animal or Human Bite

Location on the hand or the foot or over a major joint	Immunosuppression
Location on the scalp or the face of an infant	Chronic alcoholism
Puncture wound	Diabetes mellitus
Delay in treatment lasting longer than 12 hr	Corticosteroid use
	Preexisting edema in an affected extremity

An incision-and-drainage procedure is recommended when a fluctuant carbuncle is present. A thorough search for loculated areas should be undertaken to facilitate drainage of deeper accumulations of pus and to ensure adequate treatment. Wide local excision of the involved skin and subcutaneous fat is often necessary to prevent recurrent disease. An oral antistaphylococcal agent should be given. All patients with hair follicle infections should cleanse the site with chlorhexidine or an iodine-containing solution.

Infections Developing in Damaged Skin

Damage to skin as a result of animal or human bites predisposes patients to soft tissue infection. An estimated 50% of all Americans will be bitten by an animal or by another human being during their lifetime.³⁵ Animal and human bites account for approximately 1% of all emergency department visits.³⁵ Soft tissue infection is the most common complication of such bites. The risk of infection depends on the type of bite, the site of injury, the time elapsed from the bite until presentation, host factors, and the management of the wound [see Table 6].

Most animal and human bites produce minor injuries for which patients do not seek medical attention. The overall risk of infection after a bite is estimated to be 5% to 15%³⁶; however, among the subset of patients who seek medical attention, estimated infection rates range from 2% to 20% for dog bites, from 30% to more than 50% for cat bites, and from 10% to 50% for human bites.³⁷ Most patients with an infected bite can be managed on an outpatient basis with oral antibiotic therapy and elevation of the involved site.

Animal bites In the United States, dog bites account for 80% to 90% of all animal bites, cat bites for 3% to 15%.^{37,38} Nondomestic animals are responsible for only 1% to 2% of all animal bites. Patients with infections resulting from animal bites typically present with significant pain, soft tissue swelling, and tenderness; they may also have associated injuries to nerves, tendons, bones, joints, or blood vessels. Bites involving the hand are associated with an increased risk of tenosynovitis, septic arthritis, and abscess formation.³⁷

Infections that occur after a dog or cat bite are usually polymicrobial, involving a mixture of aerobes and anaerobes [see Table 7]. *P. multocida* is the major pathogen, isolated from 50% to 80% of infections related to cat bites and from 25% of those related to dog bites.^{35,37} Infection with *P. multocida* is characterized by the acute onset of severe pain, tenderness, and swelling, usually within 12 to 18 hours of the bite. In rare cases (usually involving immunocompromised patients), *Capnocytophaga canimorsus* causes soft tissue infection after a dog or cat bite. *C. canimorsus* infection can be quite serious, leading to overwhelming sepsis; the associated mortality is 25% to 30%.³⁷⁻³⁹

Wounds resulting from animal bites should immediately be washed with soap and water. When seen early, dog bites should be

copiously irrigated, debrided, and, in most circumstances, closed. Infected wounds, wounds older than 12 hours, cat bites, and bites on the hand should be left open. In all cases of infection related to an animal bite, aerobic and anaerobic cultures should be obtained from the site of infection. Tetanus immune status should be determined, and immunization against tetanus should be provided when appropriate. In cases of bites from nondomestic carnivores (e.g., bats, skunks, raccoons, foxes, or coyotes), wounds should be irrigated with povidone-iodine to reduce the transmission of rabies, and immunization against rabies should be provided.

Patients with established soft tissue infection and patients with noninfected bites who have risk factors for infection should receive antibiotic therapy [see Table 6]. A broad-spectrum antibiotic effective against aerobic and anaerobic organisms should be chosen [see Table 5]. Amoxicillin-clavulanate is the antibiotic of choice because of its broad spectrum of activity against common pathogens; trimethoprim-sulfamethoxazole, doxycycline, and ciprofloxacin are also used [see Table 5]. Infections secondary to *P. multocida* respond to oral treatment with penicillin V, amoxicillin, cefuroxime, or ciprofloxacin.³⁷ Infections secondary to *C. canimorsus* respond to penicillin, ampicillin, ciprofloxacin, erythromycin, or doxycycline. Whether antibiotics are indicated for a fresh animal bite in a patient with a low risk of infection is controversial. Because it is difficult to predict which bite wounds will become infected, some experts advocate routine antibiotic treatment of all dog bites for at least 3 to 5 days.³⁵

Human bites Human bites may be classified as either occlusional bites (in which teeth puncture the skin) or clenched-fist injuries (in which the hand is injured after contact with teeth).^{37,39} Occlusional bites carry roughly the same risk of infection as animal bites, except when they occur on the hand. Clenched-fist injuries and all hand injuries are associated with a higher risk of infection. Clenched-fist injuries typically occur at the third metacarpophalangeal joint. Penetration of the metacarpophalangeal joint capsule may occur, with subsequent development of septic arthritis and osteomyelitis.³⁵

Soft tissue infections resulting from human bites are polymicrobial, involving a mixture of aerobes and anaerobes. On average, five different microorganisms are isolated from a human-bite wound³⁷—significantly more than are usually isolated from an animal-bite wound. In addition, the concentration of bacteria in the oral cavity is higher in humans than in animals. The anaerobic bacteria isolated from human-bite wounds are similar to those that cause infection after dog and cat bites, except that *Bacteroides*

species are more common [see Table 7]. Unlike the anaerobic pathogens in dog and cat bites, however, those involved in human-bite infections often produce β -lactamases.³⁷ The predominant aerobic organisms in human-bite infections are *S. aureus*, *Staphylococcus epidermidis*, α - and β -hemolytic streptococci, *Corynebacterium* species, and *E. corrodens*. *E. corrodens* is a fastidious facultative aerobic gram-negative rod that is cultured from approximately 25% of clenched-fist injuries and frequently causes a chronic indolent infection.³⁷ It typically is susceptible to amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, doxycycline, and ciprofloxacin but resistant to dicloxacillin, nafcillin, first-generation cephalosporins, clindamycin, and erythromycin. Other pathogens may also be transmitted as a result of contact with blood or saliva, including hepatitis B and C viruses, *Mycobacterium tuberculosis*, and, possibly, HIV.

Management of human-bite wounds is similar to that of animal-bite wounds. The wound must be thoroughly irrigated, preferably with 1% povidone-iodine, which is both bactericidal and viricidal. Puncture bite wounds should be irrigated with a small catheter to achieve high-pressure irrigation. If the wound appears infected, aerobic and anaerobic cultures are obtained. Devitalized tissue should be debrided, and the wound should be left open, whether infected or not. The injured extremity should be immobilized and elevated.

Because of the high degree of contamination and local tissue damage associated with human-bite wounds to the hand, antimicrobial therapy is indicated for all such injuries. A prospective, randomized study of 45 patients with human bites to the hand seen within 24 hours after injury and without evidence of infection, tendon injury, or joint capsule penetration demonstrated that infection developed in 47% of the patients who did not receive antibiotics but in none of those who did.⁴⁰ Patients with an uncomplicated human bite to the hand should receive a broad-spectrum oral antimicrobial agent, such as amoxicillin-clavulanate (or doxycycline if they are allergic to penicillins).

Patients with human-bite wounds at sites other than the hand who have risk factors for infection [see Table 6] should also receive antimicrobial therapy. However, minor bite wounds in patients who have no risk factors for infection do not call for antibiotic therapy. As with animal-bite wounds, tetanus immunization status should be determined, and tetanus toxoid, tetanus immunoglobulin, or both should be administered as indicated.

Patients with systemic manifestations of infection (e.g., fever or chills); severe cellulitis; compromised immune status; diabetes mellitus; significant bites to the hand; associated joint, nerve, bone, or tendon involvement; or infection refractory to oral antibiotic therapy should be admitted to the hospital for I.V. antibiotic therapy.³⁷ Appropriate choices for I.V. treatment include cefoxitin, cefotetan, and piperacillin-tazobactam. Tenosynovitis, joint infections, and associated injuries to deep structures must also be treated if present.

Cellulitis

Cellulitis is an acute bacterial infection of the dermis and the subcutaneous tissue that primarily affects the lower extremities, though it can affect other areas as well (e.g., the periorbital, buccal, and perianal regions; the areas around incisions; and sites of body piercing).⁴¹ The most common causes of cellulitis are (1) soft tissue trauma from injection of illicit drugs, puncture wounds from foreign bodies or bites (animal, human, or insect), or burns; (2) surgical site infection; and (3) secondary infection of preexisting skin lesions (e.g., eczema; tinea pedis; and decubitus, venous stasis, or ischemic ulcers). Less common causes include extension of

Table 7 Organisms Most Frequently Isolated from Dog- and Cat-Bite Wounds

Aerobes	<i>Pasteurella multocida</i>
	<i>Corynebacterium</i> species
	<i>Staphylococcus</i> species
	<i>Streptococcus</i> species
	<i>Capnocytophaga canimorsus</i> (rare)
Anaerobes	<i>Bacteroides</i> species

	<i>Porphyromonas</i> species
	Peptostreptococci
	<i>Fusobacterium</i> species
	<i>Bacteroides fragilis</i>
	<i>Veillonella parvula</i>

a subadjacent infection (e.g., osteomyelitis) and bacteremia from a remote site of infection. Predisposing factors for the development of cellulitis include lymphatic disruption or lymphedema, interstitial edema, previous irradiation of soft tissue, diabetes mellitus, immunocompromise, and peripheral vascular disease.

Nonnecrotizing The overwhelming majority of patients with cellulitis have a nonnecrotizing form of the disease. Patients typically present for medical attention because of pain and soft tissue erythema, and they often have constitutional symptoms (e.g., fever, chills, or malaise). Physical examination reveals erythema with advancing borders, increased skin warmth, tenderness, and edema. Lymphangitis may also be present, manifested as an erythematous linear streak that often extends to a draining lymph node basin; associated lymphadenopathy, fever, and leukocytosis with a shift to immature forms may be apparent.

Cellulitis is usually caused by a single aerobic pathogen. The organisms most frequently responsible for cellulitis in otherwise healthy adults are *S. pyogenes* and *S. aureus*. Of the two, *S. pyogenes* is the more common and is the usual pathogen in patients with associated lymphangitis. *S. aureus* is usually present in patients with underlying chronic skin disease. Other microorganisms may cause cellulitis on rare occasions but usually only in specific clinical circumstances. *Haemophilus influenzae* sometimes causes cellulitis in children or adults infected with HIV.⁴² *Streptococcus pneumoniae* may cause this condition in patients with diabetes mellitus, alcoholism, nephrotic syndrome, systemic lupus erythematosus, or hematologic malignancies.⁴³ *P. multocida* may cause cellulitis as a complication of dog or cat bites. *S. epidermidis* is a recognized cause of cellulitis among immunocompromised patients, including those with HIV infection and those receiving organ transplants.⁴⁴ *V. vulnificus* occasionally causes cellulitis in patients who have ingested raw seafood or who have experienced minor soft tissue trauma and are exposed to sea water.⁴¹ *A. hydrophila* may cause cellulitis in patients with soft tissue trauma who are exposed to brackish or fresh water, soil, or wood.⁴¹ Cellulitis that complicates decubitus or other nonhealing ulcers is usually a mixed infection that includes gram-negative organisms.

In most situations, cellulitis is treated with empirical antibiotic regimens that include agents effective against *S. pyogenes* and *S. aureus*. Attempts to isolate a causative pathogen are usually unsuccessful; needle aspiration and skin biopsy at an advancing margin of erythema are positive in only 15% and 40% of cases, respectively.⁴⁵ Bacteremia is uncommon, and as a result, blood cultures are positive in only 2% to 4% of patients with cellulitis.^{41,46} Blood cultures are obtained selectively when the patient has high fever and chills, preexisting lymphedema, or buccal or periorbital cellulitis or when a saltwater or freshwater source of infection is suspected. In all of these clinical situations, the prevalence of bacteremia is higher.⁴⁶ Radiologic examination should be reserved for patients in whom it is difficult to exclude a deep necrotizing infection.

In an otherwise healthy adult, uncomplicated cellulitis without systemic manifestations can be treated with an oral antibiotic on an outpatient basis. Because the vast majority of cellulitides are caused either by *S. pyogenes* or by a penicillinase-producing *S. aureus*, one of the following agents is usually given: dicloxacillin, cephalexin, cefadroxil, erythromycin, or clindamycin. When MRSA infection is suspected, trimethoprim-sulfamethoxazole, a tetracycline, or clindamycin should be administered [see Table 5]. The margins of the erythema should be marked with ink to facilitate assessment of the response to treatment. For lower-extremity cellulitis, reduced activity and elevation are important ancillary measures. Appropriate analgesic agents should be given.

Table 8 Suggested Parenteral Antibiotic Regimens for Treatment of Cellulitis in Adults

Agent	I.V. Dosage
Nafcillin	2 g q. 4 hr
Cefazolin	1–2 g q. 8 hr
Clindamycin	600–900 mg q. 8 hr
Vancomycin	1 g q. 8 hr
Ampicillin-sulbactam	3 g q. 6 hr

Patients who are diabetic or immunocompromised and those who have high fever and chills, rapidly spreading cellulitis, or cellulitis that is refractory to oral antibiotic therapy should be admitted to the hospital for I.V. antibiotic therapy [see Table 8]. Nafcillin is the preferred I.V. agent. Cefazolin or piperacillin-tazobactam should be added if gram-negative organisms are suspected pathogens, as when cellulitis complicates a decubitus or a diabetic foot ulcer. Vancomycin, tigecycline, linezolid, or gentamicin should be given to patients with MRSA infections and those with serious penicillin allergies.

Necrotizing Necrotizing cellulitis is similar to nonnecrotizing cellulitis in etiology and pathogenesis but is more serious and progressive. Necrosis generally occurs when the infection is neglected or inadequately treated. The microbiology of necrotizing cellulitis is also similar to that of nonnecrotizing cellulitis, except that *C. perfringens* and other clostridial species may be involved when necrosis is present. In addition to antimicrobial therapy [see Table 8], urgent operative debridement is indicated. In other respects, necrotizing cellulitis is treated in much the same way as deep necrotizing infections are (see below). In some patients with necrotizing fasciitis, the skin is involved secondarily.

DEEP NECROTIZING INFECTIONS

Infections that involve the soft tissues deep to the skin tend to become apparent after necrosis has developed. It is possible that deep necrotizing infections begin without necrosis but progress rapidly as a result of intrinsic factors. Alternatively, such infections may develop as a result of delayed recognition attributable to the tissue depth at which the process takes place and the lack of specific early signs and symptoms. The relatively poor blood supply to subcutaneous fat makes this tissue more susceptible to microbial invasion. Contamination of the deep soft tissues occurs either through neglect or inadequate treatment of cutaneous or subcutaneous infections or through hematogenous seeding of microorganisms in an area of injury.

Most deep necrotizing soft tissue infections are polymicrobial and occur on the extremities, the abdomen, and the perineum.^{9,22,24} Necrotizing infections that involve only muscle are uncommon; therefore, necrotizing fasciitis can be considered the paradigm for these infectious processes.

The early signs and symptoms of deep necrotizing soft tissue infection are localized pain, tenderness, mild edema, and erythema of the overlying skin. These characteristics may be subtle, and this diagnosis may not readily come to mind. Sometimes, there is a history of previous injury to the area of suspected infection, which can lead to confusion about the diagnosis. The more classic findings associated with these infections—skin discoloration, the formation of bullae, and intense erythema—occur much later in the process.

It is important to understand this point so that an early diagnosis can be made and appropriate treatment promptly instituted.

Necrotizing Fasciitis

Necrotizing fasciitis is characterized by angiothrombotic microbial invasion and liquefactive necrosis.⁶ Progressive necrosis of the superficial fascia develops, and the deep dermis and fascia are infiltrated by polymorphonuclear leukocytes, with thrombosis of nutrient vessels and occasional suppuration of the veins and arteries coursing through the fascia; bacteria then proliferate within the destroyed fascia. Initially, tissue invasion proceeds horizontally, but as the condition progresses, ischemic necrosis of the skin develops, along with gangrene of the subcutaneous fat and dermis (characterized by progressive skin necrosis, the formation of bullae and vesicles, and occasional ulceration [see Figure 1]).

Myonecrosis

Myonecrosis is a rapidly progressive life-threatening infection of skeletal muscle that is primarily caused by *Clostridium* species. The classic example of myonecrosis is clostridial gas gangrene, a disease that was common in World War I soldiers who sustained extremity injuries that were contaminated with soil. Delays in definitive treatment and the use of primary closure for these contaminated wounds contributed to the severity and mortality of these infections.⁴⁷ Clostridial myonecrosis may also occur as a deep surgical site infection after contaminated operations, particularly those involving the GI tract or the biliary tract. Devitalized tissue is a per-

fect environment for clostridial proliferation. A rare form of this disease occurs in patients with colon cancer in whom myonecrosis caused by *Clostridium septicum* develops in the absence of tissue damage. Myonecrosis may also result from the spread of contiguous fascial infections.

Clostridial myonecrosis has a notably short incubation period: severe progressive disease can develop within 24 hours of contamination. This condition is characterized by acute catastrophic pain in the area of infection, with minimal associated physical findings. Systemic signs of toxicity (e.g., confusion, incontinence, and delirium) often precede the physical signs of localized infection. The skin initially is pale, then gradually becomes yellowish or bronze. Blebs, bullae, and skin necrosis do not appear until late in the course of the disease. Edema and tenderness occur early, and the absence of erythema distinguishes clostridial infections from streptococcal infection. A thin serosanguineous discharge is present in involved areas and may emanate from an involved incision. Gram stain reveals gram-positive coccobacilli with few leukocytes.

When clostridial myonecrosis is suspected or confirmed, penicillin G, 2 to 4 million U every 4 hours, should be given immediately; clindamycin, 900 mg every 8 hours, should be added. When *C. septicum* is identified on culture, a search for an occult GI tract malignancy should be made. Clostridial myonecrosis is the one soft tissue infection for which hyperbaric oxygen is recommended, though as yet, there is little evidence that this modality improves outcomes. If hyperbaric oxygen therapy is to be used, it should not be given before operative debridement.

Discussion

Etiology and Classification of Soft Tissue Infection

Soft tissue infection commonly results from inoculation of bacteria through a defect in the epidermal layer of the skin, such as may occur with injury, preexisting skin disease, or vascular compromise. Less commonly, soft tissue infection may be a consequence of extension from a subjacent site of infection (e.g., osteomyelitis) or of hematogenous spread from a distant site (e.g., diverticulitis or *C. septicum* infection in patients with colonic carcinoma). It may also occur de novo in healthy patients with normal-appearing skin, often as a result of virulent pathogenic organisms.⁴⁸

Conditions that disrupt the skin and alter its normal barrier function [see Table 2] predispose patients to bacterial contamination. Host factors may increase susceptibility to infection and limit the patient's ability to contain the bacterial inoculum. Clinically occult infection or inadequate treatment of other conditions may also lead to secondary development of soft tissue infection (as is sometimes seen in patients with diverticulitis; perirectal, pilonidal, or Bartholin's cyst abscesses; strangulated hernias; or panniculitis). Delayed or inadequate treatment of superficial infections (e.g., folliculitis, furuncles, carbuncles, cellulitis, and surgical site infections) may lead to more severe necrotizing infections.

Soft tissue infections may be classified as superficial or deep, as nonnecrotizing or necrotizing, as primary (idiopathic) or secondary, and as monomicrobial or polymicrobial. Superficial infections involve the epidermis, dermis, superficial fascia, or subcutaneous tissue, whereas deep infections involve the deep fascia or muscle [see Figure 6]. Necrotizing soft tissue infections are distinguished by the presence of extensive, rapidly progressing necrosis and high mortality. Such infections are termed necrotizing cellulitis, necrotizing fasciitis, or myonecrosis according to whether the deepest tissue layer affected by necrosis is subcutaneous tissue, deep fascia, or muscle, respectively.

Primary (idiopathic) soft tissue infections occur in the absence of a known causative factor or portal of entry for bacteria. Such infections are uncommon and are believed to result from hematogenous spread or bacterial invasion through small unrecognized breaks in the epidermis.^{48,49} Soft tissue infection caused by *V. vulnificus* is an example of a primary soft tissue infection: it is attributed to bacteremia developing after the ingestion of contaminated raw seafood. Only 10% to 15% of all necrotizing soft tissue infections are idiopathic; the remaining 85% to 90% are secondary infections, developing as a consequence of some insult to the skin that predisposes to infection. Secondary soft tissue infections may be further categorized as posttraumatic, postoperative, or complications of preexisting skin conditions.

Soft tissue infections are classified as monomicrobial when they are caused by a single organism and as polymicrobial when they are caused by multiple organisms. Most superficial soft tissue infections are caused by a single aerobe, usually *S. pyogenes* or *S. aureus*. Exceptions to this general rule include infections caused by animal or human bites, cellulitis associated with decubitus or other non-healing ulcers, and infections in immunocompromised patients. These infections are typically polymicrobial, often involving aerobic or facultative gram-negative organisms and anaerobes in addition to aerobic gram-positive bacteria.

Deep necrotizing soft tissue infections are polymicrobial 70% to 75% of the time. They are caused by the synergistic activity of facultative aerobes and anaerobes [see Figure 7].^{50,51} *S. aureus*, *S. pyogenes*, and enterococci are the most common gram-positive aerobes. *Escherichia coli* is the most common gram-negative enteric organism. *Bacteroides* species and peptostreptococci are the most common anaerobes.^{9,27,51} The remaining 25% to 30% of deep necrotizing infections are monomicrobial. Most primary necrotizing soft tissue infections are monomicrobial.⁴⁸ These infections are

Figure 7 Meleney’s ulcer is characterized by central necrosis, erythema, and edema.

more fulminant and are notable for their acute onset, rapid progression, and systemic toxicity. Their characteristic clinical manifestations are related to exotoxin production by the pathogen involved [see Table 9 and Pathogenesis of Soft Tissue Infections, below]. *S. pyogenes* is the pathogen in more than half of monomicrobial infections; *S. aureus*, *C. perfringens*, *V. vulnificus*, and *P. aeruginosa* are less common.

Pathogenesis of Soft Tissue Infections

Soft tissue infections generally induce localized inflammatory changes in the involved tissues, regardless of the species of bacteria involved. As the infection progresses, tissue necrosis occurs as a result of (1) direct cellular injury from bacterial toxins, (2) significant inflammatory edema within a closed tissue compartment, (3) thrombosis of nutrient blood vessels, and (4) tissue ischemia.

The exotoxins produced by gram-positive cocci and some gram-negative bacteria are powerful proteolytic enzymes. *S. pyogenes* produces hemolysins, fibrinolysins, hyaluronidases, and streptolysins. *S. aureus* and *P. aeruginosa* produce coagulases that result in local tissue damage and necrosis. *C. perfringens* produces numerous exotoxins. The α -toxin, a lecithinase enzyme, is highly lethal: it destroys cell membranes, causes hemolysis, and alters capillary permeability. Other clostridial toxins lyse red blood cells and have direct cardiotoxic effects. These toxins also cause platelet aggregation and fibrin deposition, with resultant vascular thrombosis and necrosis. Production of the θ -toxin leads to intravascular leukostasis and inhibits diapedesis of white blood cells into infected tissue. This unique collection of bacterial toxins accounts for the rapid progression of *C. perfringens* infection in a setting of minimal inflammatory changes.

That most necrotizing soft tissue infections involve multiple bacterial species strongly suggests that bacterial synergy plays an important role in their pathogenesis. Toxin-induced cellular necrosis establishes an anaerobic environment that facilitates the growth of both facultative and anaerobic bacteria. These anaerobes elaborate additional enzymes and other by-products that facilitate tissue invasion and destruction.

Preexisting local tissue damage frequently serves as a nidus for soft tissue infection. The reduced oxygen tension of this abnormal environment allows pathogens to proliferate. In addition, various

patient factors predispose susceptible individuals to these infections. Chronic illnesses can contribute to a diminished immunologic response. Peripheral vascular disease impairs the local blood and oxygen supply. Diabetes mellitus inhibits WBC function. Chronic pulmonary disease can result in systemic hypoxemia. Patients with congestive heart failure or significant coronary artery disease may be unable to increase their cardiac output in response to infection. Malnutrition can result in a lack of nutrients and critical enzymatic cofactors involved in the normal cellular response to infection. Each of these patient factors impairs the host response and thereby increases the likelihood that infection will develop.

In the 1920s, Meleney demonstrated that injection of animals with pathogens isolated from patients with infectious gangrene reproduced the characteristics of infection.² Decades later, the importance of bacterial synergy and exotoxins was demonstrated in experiments performed by Seal and Kingston,⁵² who showed that a spreading infection developed in 12% of animals that received an intradermal injection of group A β -hemolytic streptococci. When *S. aureus* was coinjected with β -hemolytic streptococci, spreading infections developed in 50% of animals, and when the α -lysin of *S. aureus* was coinjected with streptococci, spreading infections developed in 75%.

Streptococcal Toxic-Shock Syndrome

Hemolytic streptococci were originally described by Meleney as the cause of a “synergistic gangrene.”² The current resurgence of necrotizing soft tissue infections attributed to so-called flesh-eating bacteria probably represents an adaptation of group A streptococci to the contemporary environment.⁵³ Streptococcal toxic-shock syndrome (STSS) is defined as the isolation of group A streptococci from a normally sterile body site in conjunction with hypotension and either renal impairment, acute respiratory distress syndrome, abnormal hepatic function, coagulopathy, extensive tissue necrosis, or an erythematous rash.⁴⁵ STSS is considered the probable diagnosis when these abnormalities occur in conjunction with isolation of group A streptococci from nonsterile body sites. More than 60% of patients with STSS have bacteremia. STSS has been shown to be a major risk factor for mortality among patients with necrotizing soft tissue infections.⁵⁴

Population-based studies in North America and Europe documented a nearly fivefold increase in group A streptococcal infections between the late 1980s and 1995.⁵⁵ The current incidence of group A streptococcal infections in the population of Ontario, Canada, is estimated to be 1.5 per 100,000.⁵⁵ STSS develops in

Table 9 Major Exotoxins Associated with Organisms Causing Monomicrobial Necrotizing Soft Tissue Infection

Bacterium	Exotoxins
<i>Streptococcus pyogenes</i>	Pyrogenic exotoxins A and B, hemolysin, fibrinolysin, hyaluronidase, streptokinase
<i>Staphylococcus aureus</i>	Hemolysins (intravascular hemolysis and local tumor necrosis), coagulase
<i>Pseudomonas aeruginosa</i>	Collagenase (local tissue damage and necrosis)
<i>Clostridium perfringens</i>	α -Toxin (lecithinase causing tissue necrosis, intravascular hemolysis, hemoglobinemia, and acute renal failure)

Figure 8 Shown is the superficial appearance of streptococcal gangrene of the posterior thigh.

approximately 10% to 15% of these patients, necrotizing fasciitis in about 6%.⁵⁶ It is likely that the rise in serious group A streptococcal infections reflects an antigenic shift that has increased the virulence of these organisms.

Soft tissue infections associated with STSS typically involve an extremity. Approximately 70% of patients will progress to necrotizing fasciitis or myositis and will require operative treatment. Only about 50% of patients with streptococcal soft tissue infections have a demonstrable portal of entry for bacteria.^{48,57}

Severe pain is the most common initial symptom of STSS. It is of sudden onset and generally precedes tenderness or other physical findings. Fever is another common early sign. About 80% of STSS patients show clinical signs of soft tissue infection (e.g., localized swelling, erythema, and tenderness) [see Figure 8]. In approximately 50%, blood pressure is initially normal, but hypotension invariably develops within 4 to 8 hours after presentation.

Hemoglobinuria and an elevated serum creatinine concentration are hallmarks of renal involvement. Even when adequate resuscitation is provided and antibiotics and vasopressors are given, hypotension persists in the overwhelming majority of patients. Renal dysfunction can persist or progress for 48 to 72 hours despite treatment. Hypoalbuminemia and hypocalcemia are common. Mild leukocytosis is present initially; however, the percentage of immature neutrophils is generally 40% or higher.

S. pyogenes can be classified into more than 80 different strains, or M types, on the basis of the M proteins expressed. M proteins impede phagocytosis of streptococci and induce vascular leakage by forming complexes with fibrinogen.⁵⁸ They also cleave nicotinic acid dinucleotide (NAD), thereby interrupting elemental cellular

processes. The M proteins M1 and M3 are associated with the majority of streptococcal necrotizing soft tissue infections.⁵³ Streptococcal pyrogenic exotoxins (SPEs) are produced by most streptococci that cause severe soft tissue infection and can be transmitted by bacteriophages to different M types. They are the cause of the fever, shock, and tissue injury associated with these infections. SPE-A and SPE-B induce the synthesis of tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and IL-6. Peptidoglycan, lipoteichoic acid, and killed organisms also are capable of inducing TNF- α production.

It has been proposed that M proteins or SPEs act as superantigens. These exotoxins, along with certain staphylococcal toxins (e.g., toxic-shock syndrome toxin-1 [TSST-1] and staphylococcal enterotoxins), can stimulate T cell responses through conventional antigen-presenting cells, as well as through direct binding to the V β region of the T cell receptor. Conventional T cell activation through antigen-presenting cells is a multistage process that stimulates a relatively small percentage of T cells and limits the magnitude of the resultant cytokine response. In contrast, superantigens bypass the normal antigen presentation pathway and do not undergo phagocytosis. The superantigen processing pathway can stimulate more than a thousand times more T cells than the conventional antigen pathway and thus can trigger a massive release of cytokines. The idea that T cell stimulation by superantigens can explain the severe degree of illness and exaggerated response seen in these patients is attractive, but at present, there is no definitive proof that this process occurs in humans.

Although *S. pyogenes* is susceptible to penicillin and other β -lactam antibiotics in vitro, clinical treatment failure sometimes occurs when penicillin is used alone against *S. pyogenes* infections.⁵³ Such failure is a particular problem with more aggressive group A streptococcal infections and may be attributable to the large inoculum size (the so-called Eagle effect). These large inocula reach the stationary growth phase very quickly. Penicillin and other β -lactam antibiotics are ineffective in the stationary growth phase because of the reduced expression of penicillin-binding proteins in this phase. Moreover, toxin production is not inhibited by β -lactam antibiotics during the stationary growth phase. In contrast, antibiotics that inhibit protein synthesis have been associated with improved survival after serious group A streptococcal infections.

Clindamycin is more effective than β -lactam agents in managing experimental and clinical infections caused by group A streptococci, particularly when necrosis is present.⁵⁹ Clindamycin inhibits protein synthesis, and its efficacy is unaffected by inoculum size or the stage of bacterial growth. In particular, it suppresses bacterial toxin synthesis and inhibits M-protein synthesis, thus facilitating phagocytosis of *S. pyogenes*. Clindamycin also suppresses synthesis of penicillin-binding proteins, and it can act synergistically with penicillin.

3 PRINCIPLES OF WOUND MANAGEMENT AND SOFT TISSUE REPAIR

Eric G. Halvorson, MD, and Joseph J. Disa, MD, FACS

Difficult Wounds

Problem wounds are characterized by one of the following: large size that precludes direct primary closure, gross infection or uncertain bacteriologic status, or threatened loss of critical structures exposed as a result of insufficient

soft tissue coverage. Surgically created wounds, which generally pose less of a problem from a bacteriologic standpoint than traumatic wounds, are best managed by an immediate coverage procedure when direct closure is impossible.

Traumatic wounds are more difficult to evaluate than surgical wounds for several reasons. First, the potential for infection is high because of the environment in which the wound is created, the mechanism of injury, and the time that elapses before operative intervention. Second, the mechanism of injury (e.g., crush, avulsion, or gunshot) may extend the zone of injury beyond what is immediately apparent [see Figure 1]. Serious

a

b

c

Figure 1 (a) A so-called bumper injury of the leg is shown after initial débridement and bony stabilization (2 days after injury). (b) After the second débridement, the true extent of devitalization of bone and soft tissue is apparent (4 days after injury). (c) A latissimus dorsi free flap has been used to reconstruct the soft tissue defect (5 days after injury).

Approach to Surgical Reconstruction

postoperative infection may develop in these cases if definitive wound coverage is provided in the absence of adequate débridement. Third, whereas accurate assessment of the chances for recovery of specific structures within the wound is vital for selecting the optimal method of treatment, such assessment is often difficult immediately after injury.

EVALUATION

The initial step in the management of problem wounds is to decide whether the wound is suitable for immediate soft tissue coverage. Wounds that are surgically created during the course of an elective procedure are almost always best treated with primary definitive coverage. Traumatic wounds that present within 1 or 2 hours of injury and have a minimal crush component are also best treated with a primary definitive coverage procedure after thorough débridement (if the patient's hemodynamic status permits).

Injuries with a significant crush component and exposure of critical structures (e.g., nerves, vessels, tendons, or bone) are best treated more aggressively. In these cases, thorough débridement requires considerable surgical experience because the tendency is to débride inadequately. The accuracy with which tissue viability can be assessed varies from one type of tissue to another. For example, skin can be evaluated by its color, the nature of its capillary refill, the quality of its dermal bleeding, or its bleeding response to pinprick. After intravenous fluorescein injection, skin viability can also be assessed qualitatively, with a Wood light, or quantitatively, with a dermofluorometer. Muscle is the most difficult tissue to evaluate. Color, capillary bleeding, and contractile response to stimulation are not always reliable indicators of muscle viability. In severe injuries, they can be misleading. Inadequate débridement may lead to severe consequences resulting from infection. Therefore, serial débridement at 24- to 48-hour intervals is essential for accurately establishing the limits of muscle injury. Efforts should be made during débridement to preserve tissues such as major nerves and blood vessels unless they are severely injured. These structures are vital for function and are of small mass compared with other tissues (e.g., skin, fat, and muscle) at risk for necrosis and subsequent infection.

Wound débridement, therefore, should involve careful analysis of the injury from an anatomic point of view; débridement should not consist of indiscriminate excision of blocks of tissue. Between débridement procedures, the wound should be treated with sterile dressing changes or negative-pressure wound therapy (NPWT) if conditions permit. A definitive soft tissue coverage procedure should then be performed as soon after the initial injury as wound conditions permit. When thorough débridement and definitive coverage can be completed within less than 1 week, the wound will generally heal uneventfully. Inadequate débridement frequently results in the loss of any additional tissue invested to achieve acute soft tissue coverage. The wound becomes grossly infected, and important functional structures within the wound are reexposed.

Infected surgical wounds, neglected wounds, or other complex wounds in which initial wound management fails should be débrided and then treated by open methods. Proper care of these wounds is aimed at converting estab-

lished gross infection to a much lower level of bacterial contamination, which is then compatible with successful secondary wound closure. For example, advances in the use of NPWT [see Initial Treatment, Negative-Pressure Wound Therapy, *below*] have simplified the management of complex lower extremity traumatic wounds, reducing the use of free tissue transfer.¹

INITIAL TREATMENT

Débridement

Devitalized tissue provides an ideal culture medium for bacteria and isolates them from host defense mechanisms. Surgical débridement must be performed aggressively—and on a serial basis if necessary—to remove all necrotic tissue.

High-Pressure Irrigation

A useful adjunct to débridement is high-pressure irrigation, which has been shown experimentally to reduce wound infection rates significantly.^{2,3} Some argue that small particulate materials may get pushed deeper into a wound bed; therefore, this technique should not be used indiscriminately. It is recommended as an adjunct once thorough débridement has been performed manually.

Quantitative Bacteriology

The degree of bacterial wound contamination can be accurately quantified. The standard technique of quantitative bacteriology requires several days to complete and is therefore of somewhat limited utility in the management of acute wounds. In addition to a count, it provides identification and antibiotic sensitivities of the organism. As an alternative, quantitative bacteriology can be performed by using the rapid slide technique, which provides valuable information about the wound within 20 minutes.^{4,5} The level of bacterial contamination has been shown to be a significant predictor of outcome in wound closure by either skin graft or flap coverage techniques. According to the golden period principle of wound closure, a minimum time interval is necessary for bacteria to proliferate to a certain threshold level. Contaminated wounds take a mean time of about 5 hours to reach a bacterial count of 10^5 /g of tissue. Attempts to close wounds that have counts higher than 10^5 /g of tissue will fail 75 to 100% of the time, whereas attempts to close wounds with lower counts are successful more than 90% of the time.⁶ β -Hemolytic streptococci are an exception in that much lower concentrations of these organisms consistently result in failure of wound closure. When a β -hemolytic streptococcus is the dominant isolate, the wound should generally be treated openly until cultures become negative. Good clinical judgment often makes quantitative bacteriology unnecessary, and it is not used frequently. In many modern microbiology laboratories, it is no longer available.

Systemic and Topical Antibiotics

The role of systemic antibiotics in wound management is not clearly defined. Broad-spectrum antibiotics should be given in cases of severe trauma as a prophylactic dose prior to surgery. Certain antibiotics provide broad-spectrum activity when applied topically. Neomycin, 10 mg/mL, or a

combination of bacitracin, 50 U/mL, and polymyxin B, 0.05 mg/mL, kills most common wound pathogens. These solutions can be used when wet dressings are indicated, or as described in the chapter “Management of the Burn Wound” [see 7:15]. In the past few years, numerous antibacterial dressings have been developed, including an antibacterial NPWT sponge. Such dressings may prove useful in the treatment of open, contaminated wounds; however, discussion of these products is outside the scope of this chapter.

Topical Antiseptics

A variety of topical antiseptics have been used empirically in wound care. In the concentrations usually recommended, however, these solutions are detrimental to wound healing. Povidone-iodine (1%), hydrogen peroxide (3%), acetic acid (0.25%), and sodium hypochlorite (0.5%) all have been shown to be lethal to fibroblasts, as well as to bacteria. More dilute concentrations of povidone-iodine (0.001%) and sodium hypochlorite (0.005%) are effective against bacteria while being safe for fibroblasts.⁷ A number of these agents also inhibit normal white blood cell function in the wound.

Damp Dressings

Open wounds can be treated with damp dressings, generally consisting of gauze soaked in saline or an acceptable topical antiseptic, and then wrung out until just damp. Damp-to-damp dressings prevent desiccation of exposed vital structures or freshly placed skin grafts. Damp-to-dry dressings are useful for assisting in daily wound débridement. These dressings are allowed to dry on the wound; when they are removed, adherent fibrinous debris is removed with the dressing. Damp dressings of either type should be changed at least twice a day.

Small wounds can be expected to close by contraction and secondary epithelialization after appropriate open management with the techniques described. Large wounds will improve with aggressive open care but will then stabilize into a chronic state of wound colonization of varying degrees. A soft tissue coverage procedure may then be necessary to complete closure in these cases.

Negative-Pressure Wound Therapy

In the past 10 years, the vacuum-assisted closure (VAC) device (VAC Dressing System, Kinetic Concepts Inc., San Antonio, TX) has gained widespread acceptance for the treatment of open wounds. Because this device does not accomplish débridement to any significant degree, it should be applied only to a clean wound that has no necrotic debris or infection present. If any significant necrotic tissue remains after sharp débridement, wet-to-dry dressings may be employed until the wound is clean and granulating. Dressing changes are typically carried out every 2 or 3 days; this is a significant advantage, given that conventional dressing changes are generally done at least twice daily. Exudate is removed and quantified by the suction device, and more robust wound granulation and contraction can be observed. After treatment with a VAC device, wound closure can be accomplished secondarily with a skin graft, local flaps, or free tissue transfer, depending on the clinical situation. The disadvantages of NPWT include the need for specialized equipment and training and the increased cost.

SELECTION OF COVERAGE PROCEDURE

The main goals of coverage procedures in the management of both acute and chronic wounds are (1) to achieve a healed wound and (2) to avoid infection. The treatment of functional problems is generally deferred for secondary reconstruction.

The method of coverage depends on whether vital structures (e.g., vessels, tendons, nerves, and bone) are exposed in the wound. If no vital structures are exposed, skin graft coverage is indicated. Skin grafts can also be used over tendon if the paratenon is intact, over nerve if the epineurium is intact, and over bone if the periosteum is intact. Skin grafts are the most expendable type of soft tissue available for the coverage of open wounds. They allow the wound to heal completely and set the stage for secondary reconstruction, during which more valuable tissue can be used to achieve other goals at minimal risk. When vital structures are exposed in the wound, a flap is preferred because it provides more substantial soft tissue coverage of the structure. The choice of flap depends on the location of the wound and on its overall size, depth, and topographic configuration (see below).

Skin Grafts

Skin grafts may be either partial thickness (i.e., split thickness) or full thickness. Split-thickness grafts are preferred for wounds with a large surface area. Full-thickness grafts are suitable only for small defects because their donor sites must be closed primarily; the most common donor sites for full-thickness grafts are the ears, upper eyelids, neck, and groin. Full-thickness grafts contract less with time than split-thickness grafts and are therefore particularly suitable for wounds of the hands, extremity flexion creases, nose, eyelids, and other areas of the face.

Successful healing of skin grafts requires immobilization of the recipient site to prevent shearing in the plane between the graft and the wound bed. Although complete immobilization is desirable, the required dressings may preclude observation of a wound that is known to be significantly contaminated. In such cases, a meshed split-thickness graft is indicated, and the wound should be treated in an open fashion. A meshed graft can be placed directly over the muscle of a flap and secured over its irregular contour with staples [see Figure 2]. Because the graft is meshed, serum can escape between the interstices and there is little risk of separation from the underlying tissue. A meshed graft is also less vulnerable to disruption by shear forces. An additional advantage of a meshed graft is that it permits the wound to be treated with wet dressings if there is still risk for

Figure 2 A meshed (1.5:1 ratio) skin graft has been secured to the irregular contour of a muscle free flap with staples. No additional immobilization of the graft is needed. The interstices of the graft allow free drainage of serous exudate from the muscle.

infection. A mesh expansion ratio of 1.5:1 is generally preferred, except when the surface area of the wound is very large and the availability of donor sites is limited.

Flaps

Flaps consist of tissues that have a self-contained vascular system. They permit a more substantial transfer of tissue bulk than do skin grafts and may consist of skin and subcutaneous tissue, fascia, muscle, bone, or a combination of several tissue types. Local flaps consist of tissue that is mostly detached from surrounding tissue but retains enough connection to preserve an adequate blood supply to the entire flap. Local flaps are either transposed, rotated, or advanced into adjacent defects for purposes of reconstruction. Island flaps are local flaps that are based only on their skeletonized axial blood supply. Once created, an island flap is transferred through a subcutaneous tunnel into the defect. The skeletonized pedicle remains in the subcutaneous space while the cutaneous portion of the flap fills the defect. Free flaps, in contrast, are totally detached; their blood supply is reconnected at the recipient site by means of surgically performed microvascular anastomoses between recipient-site blood vessels and the major vessels that supply the flap.

Blood Supply

The earliest flaps in common use were skin flaps that had what is known as a random-pattern type of circulation [see Figure 3a], in which blood is supplied by the subdermal capillary plexus rather than by a named vessel.⁸ The precarious nature of the blood supply of such flaps severely limited flap design and resulted in a preoccupation with suitable length to width ratios. Greater length to width ratios became

possible after the empirical discovery that a more vigorous circulation develops in flaps raised in stages (the delay phenomenon).⁹ The next flaps to come into common use had an axial-pattern type of circulation, in which a sizable artery coursed directly to a specific cutaneous territory [see Figure 3b]. The groin was the first region where this arrangement was carefully described, and it remains a useful source of flaps for selected applications. Because longer flaps can be made in areas where the blood supply has an axial pattern, the length to width ratio and the delay phenomenon became less important issues.¹⁰ Identification of an axial-pattern blood supply to a given graft allows so-called islanding of the graft from the donor site except for the vascular connection, which is preserved. Such island flaps have greater mobility than flaps with a less attenuated attachment to the donor site.

A third type of flap was based on the myocutaneous blood supply, a network of vessels that perforate muscles vertically and supply the overlying skin [see Figure 3c and Figure 3d]. These vessels are not necessarily the exclusive supply to the skin in a specific region, but they are able to support the skin entirely when other sources of blood supply are eliminated. Investigation of the body musculature showed that there were at least five basic patterns of blood supply to muscle, distinguished by the existence of and balance between primary pedicles and secondary sources of blood supply [see Figure 4]. Some muscles can be rotated or transposed as myocutaneous flaps on the basis of either their dominant or their secondary blood supply (e.g., the pectoralis major and the latissimus dorsi). Some muscles have two dominant supplies and can be transposed on either one (e.g., the rectus abdominis). Other muscles do not reliably support skin territories supplied by minor pedicles (e.g., the gracilis).

Other patterns of cutaneous blood supply are now well recognized. Fasciocutaneous flaps with high length to width ratios can be reliably raised on the trunk, arms, and legs. The blood supply of deep fascia appears to consist of both a deep and a superficial fascial plexus. These vessels connect both to perforating vessels from the underlying muscles and to the subcutaneous tissue vessels above them.¹¹ At least three types of fasciocutaneous flaps may be distinguished on the basis of the fascial blood supply to the skin [see Figure 5].¹²

In some areas, fascia supplies overlying subcutaneous tissue and skin more directly. Such a blood supply is most evident in the extremities, where direct branches from major vessels course through intermuscular septa to reach the deep fascia and supply the overlying skin and subcutaneous tissue. The forearm is a clinically important donor site because thin septocutaneous flaps fed by the radial artery can be raised as either pedicled or free flaps. Other examples of fasciocutaneous flaps include the lateral arm septocutaneous flap, fed by the profunda brachii artery; the scapular flap, fed by the circumflex scapular artery [see Figure 3d]; the fibular osteofasciocutaneous flap, fed by the peroneal artery; and the anterolateral thigh flap, fed by the descending branch of the lateral circumflex femoral artery.

The 21st century has seen the popularization of “perforator” flaps, which are based on musculocutaneous branches (or perforators) of named, axial vessels. In the early years of

Figure 3 (a) The blood supply of random-pattern skin flaps is limited; only small flaps (e.g., thenar flaps, shown here) are consistently reliable. (b) Shown is an axial-pattern skin flap. (c) The skin and subcutaneous tissue of a myocutaneous flap can exist as a complete island because the blood supply is derived from vertical muscular perforators. (d) Shown are a large free flap of scapular area skin and the entire latissimus dorsi. The subscapular vessels that connect the two will supply both components of the flap after microvascular anastomoses.

microsurgery, success was defined by a lack of microvascular thrombosis. As experience was gained and rates of microvascular anastomotic failure decreased, focus was then turned on limiting donor-site morbidity. Several myocutaneous flaps used primarily for their skin and subcutaneous components were modified such that musculocutaneous perforators supplying the overlying fat and skin were dissected through the muscle down to the pedicle origin, thus preserving muscle and function. Common perforator flaps include the deep inferior epigastric perforator flap, or DIEP flap, and the superior and inferior gluteal artery perforator flaps, or SGAP and IGAP flaps. These flaps are commonly performed for breast reconstruction. The anterolateral thigh flap, or ALT flap, is supplied by a musculocutaneous perforator of the descending branch of the lateral circumflex femoral artery roughly two thirds of the time and by a septocutaneous branch one third of the time.

TYPES OF LOCAL FLAPS

Transposition Flaps

A flap that is moved laterally into the primary defect is called a transposition flap. The essential concept in the design of such a flap is to ensure that the flap is long enough to cover the entire defect, so that the transfer can be done without tension [see Figure 6].

The skin is marked and incised with a scalpel, and dissection is carried through the subcutaneous fat. The flap is retracted with a skin hook, and dissection is performed with blunt scissors until the flap is elevated sufficiently to allow it to be transposed into the defect without tension. The secondary defect is closed primarily; alternatively, depending on the location of the donor area and the degree of skin tension present there, a skin graft may be indicated. As with any local flap, wide undermining of the surrounding tissues may be

Figure 4 Schematized are the five basic patterns of blood supply to muscle. Individual muscles are classified on the basis of the dominance, number, and size of the vessels that supply them. Type I is supplied by a single dominant pedicle. Type II is supplied by one dominant vessel and several much smaller vessels. Type III is supplied by two dominant pedicles. Type IV is supplied by multiple vessels of similar size. Type V is supplied by one dominant pedicle and several smaller segmental vascular pedicles.

Figure 5 At least three types of fasciocutaneous flaps exist, categorized by blood supply configuration. Type A is supplied by multiple small, longitudinal vessels coursing with the deep fascia. These flaps must retain a base of a certain width and cannot be raised as islands (e.g., longitudinally oriented flaps of skin and fascia on the lower leg). Type B is supplied by a single major vessel within the fascia (e.g., scapular flap). Type C is supplied by multiple perforating segments from a major vessel coursing through intermuscular septa (e.g., forearm flaps).

necessary for closure of the defect and the donor site. Closure is then performed in two layers.

Bilobed flap A bilobed flap is a transposition flap consisting of two lobes of skin and subcutaneous tissue based on a common pedicle [see Figure 7]. It is often used to correct

nasal defects involving the lateral aspect, the ala, or the tip. The keys to a successful bilobed flap are (1) accurate design and (2) wide undermining of the surrounding tissue in the submuscular plane to allow a smooth transposition. The primary lobe is usually at an angle of 45° or less to the defect;

Figure 6 After excision of the defect, a transposition flap of adequate length is designed and elevated in the subcutaneous plane. The flap is moved laterally into the defect and inset. It may be necessary to excise a dog-ear of excess skin at the tip of the flap harvest site.

Figure 7 A flap with two lobes is created, with the first lobe the same size as the defect and the second lobe substantially (50%) smaller than the first. The flap is elevated in the submuscular plane. Wide undermining at this level is necessary for tension-free transposition. The first lobe covers the initial defect, and the second covers the defect from the first. The second lobe is placed in an area of loose skin, and its area of origin is closed primarily.

the secondary lobe is designed to achieve closure of the donor defect and is substantially smaller than the primary lobe. The angle between the two is 90° to 100°. Both flaps are raised simultaneously in the submuscular plane. Wide undermining of the area (also in the submuscular plane) minimizes tension. The primary lobe of the bilobed flap is transposed into the initial defect, the secondary lobe is transposed into the donor defect left by the primary lobe, and the defect left by the secondary lobe is closed primarily. Closure is accomplished with 5-0 or 6-0 nylon.

Rhomboid flap (Limberg flap) A rhomboid flap is a transposition flap that is designed in a specific geometric fashion [see Figure 8]. The initial defect is converted to a rhomboid, with care taken to plan the flap in an area with minimal skin tension. The rhomboid must be an equilateral parallelogram with angles of 60° and 120°; this design allows the surgeon to excise less tissue than would be needed for an elliptical flap. One face of the rhomboid constitutes the first side of the flap (YZ). The short diagonal of the rhomboid is then extended outward for a distance equal to its own length.

This extension should be oriented along relaxed skin tension lines, perpendicular to the line of maximum extensibility; it constitutes the second side of the flap (XY). Next, a line parallel and equal in length to YZ is drawn from X to outline the third side of the flap. Correct orientation of the rhomboid is vital for achieving flap repair with minimal tension, particularly with respect to the line of maximum extensibility: it is along this base line that maximum tension results when the donor defect is closed. Once the flap has been correctly designed and elevated, it is transposed into the defect. Closure is done in two layers.

Rhomboid flaps work best on flat surfaces (e.g., the upper cheek, the temporal region, and the trunk). Extra attention to flap design is necessary when an attempt is made to close a defect over a convex surface with a rhomboid flap; improper flap design leads to excessive tension and potential flap necrosis.

Rotation Flaps

A flap that is rotated into the defect is called a rotation flap.^{13,14} This type of flap is commonly used to repair a defect

Figure 8 (a) The defect is converted to a rhomboid, with all four sides of equal length and angles of 60 and 120. An extension XY is made that is the same length as the short diagonal of the rhomboid, and a line of equal length is drawn from X paralleling YZ. (b) The flap is oriented so that XY follows the relaxed skin tension lines (RSTL) and YZ the line of maximum extensibility (LME). (c) The flap is inset.

on the scalp, where large flaps must be designed to overcome the inelasticity of scalp tissue. A rotation flap takes the form of a semicircle, of which the defect occupies a wedge-shaped segment [see Figure 9]. The original defect is converted to a triangular shape (ABC). One side of the triangular defect (AC) is extended to a point (D) that will serve as the pivot point for the flap. The distance between A and D should be at least 50% greater than that between A and C. A semicircular line extending from C to D is then defined.

The flap is incised with a scalpel, elevated, and rotated. As with all local skin flaps, wide undermining of the surrounding tissue may be necessary to allow tension-free rotation and wound closure. The flap is secured with a two-layer closure; the secondary defect may be closed primarily. Sometimes a so-called back cut is required to gain adequate rotation. The most common technical error with rotation flaps is improper design: a flap that is too small will not cover the defect adequately.

Advancement Flaps

Advancement flaps are moved directly forward into a defect without either rotation or lateral movement. The single-pedicle advancement flap is a rectangular or square flap of skin and subcutaneous tissue that is stretched forward. The flap is oriented with respect to the local skin tension, with care taken to plan the advancement in an area where the skin is extensible. A rectangular defect is created, and the flap is elevated in an area of loose skin and advanced to cover the defect [see Figure 10]. When closure is performed, some excess skin (dog-ears) at the base of the flap (Burow triangles) may have to be excised.

V-Y advancement flap The -Y advancement flap is a modification of a basic advancement flap [see Figure 11]. The use of a -Y advancement flap eliminates the need to revise the dog-ears that sometimes result with rotation flaps. When possible, the flap should be oriented in accordance with the line of maximum extensibility. Its length should be 1.5 to 2 times that of the defect in the direction of the closure.

Incisions are made completely through skin. As with other flaps, skin hooks are used to retract the skin flap, and blunt

Figure 9 (a) The defect is converted into a wedge. One side (AC) is extended to a pivot point D, so that AD is at least 50% longer than AC. A semicircle from C to D is defined. (b) The flap is elevated, rotated, and inset. (c, d) If there is too much tension, a back cut may be necessary to release the flap and allow rotation. Care is taken not to make the back cut excessively long; to do so could devascularize the flap.

Figure 10 (a) A flap whose shape corresponds to that of the defect is elevated in the subcutaneous plane and advanced into the defect. (b) Excision of Burow triangles (excess skin at the flap base) may be necessary to permit advancement.

Figure 11 (a) A V-shaped flap is created whose length is 1.5 to 2 times that of the defect. With subcutaneous connections to the skin preserved (because these constitute the blood supply to the flap), the flap is advanced into the defect. (b) The V incision is converted to a Y as the base is closed primarily.

scissors dissection is then performed. The point of the on the flap is the area where tightness is most frequently encountered; this area may have to be released to facilitate advancement. Care must be taken not to undermine the advancing flap excessively: doing so may impair or interrupt the blood supply to the flap and result in necrosis. Once adequately advanced, the flap is sutured at the advancing edge and at the base of the Y.

Z-Plasty

When reconstruction is indicated for small, localized scars, soft tissue coverage is generally sufficient. With such coverage, there is no threat of breakdown leading to exposure of important structures; instead, the reconstructive problem is generally functional. An example is a flexion crease contracture, which is commonly seen after a burn injury. A local procedure that rearranges the existing tissue can relieve the tension by making more tissue available in one direction, even though the amount of tissue in the area is not actually increased.

Figure 12 (a) The central limb of the Z is placed along the line of contracture. Incisions diverging from the scar at a 60 angle will yield an increase of approximately 75% in the direction of the central limb. (b) The flaps are transposed. (c) The length has been increased in the desired direction, and the original Z design has been rotated 90 and reversed.

The -plasty [see Figure 12] is an example of such tissue rearrangement.¹⁵ Two triangular flaps are designed so that they have in common a central limb aligned in the direction along which additional length is desired. For example, the limb may be placed along the line of a contracture. Two lines, approximately equal in length to the central limb, are drawn from either end of the limb, diverging from it at equal angles varying from 30° to 90°. The degree of lengthening obtained is determined by the size of this angle [see Table 1]. In theory, maximal length gain is achieved by using the largest angle possible, but in practice, the maximum usable angle is determined by the limits of skin elasticity. A 60° angle, which is commonly used, will result in a 75% gain in length along the central limb. Triangular flaps are elevated, and the fibrous tissue band responsible for the contracture is divided. The triangular flaps are transposed and inset, yielding increased length in the desired direction, with the original rotated 90° and reversed.

Although -plasty is conceptually simple, it is not necessarily easy: experience is necessary for the surgeon to realize the limitations of technique and appreciate the subtleties of proper design. Important considerations in the use of -plasty include appropriate determination of the length of the central limb and correct orientation of the limbs so that the new central limb formed after transposition is parallel to skin tension lines. Multiple -plasties may be useful for some localized scars.

Table 1 Z-Plasty: Incision Angle and Degree of Lengthening Theoretically Possible

Incision Angle (degrees)	Theoretical Amount of Lengthening (%)
30	25
45	50
60	75
75	100
90	120

Figure 13 Defects in the central portion of the body are treated with myocutaneous flaps primarily; defects of the peripheral areas are treated with either local flaps or free flaps. In some areas, several options exist, and the choice is influenced by the size of the defect and the specific tissue requirements.

Local flaps versus free flaps The choice between a local flap and a free flap is determined by the amount and the type of tissue needed, as well as by the availability of flaps in the immediate area of the wound [see Figure 13]. The availability of local flaps, in turn, is determined by the nature of the regional blood supply. The vascular anatomy of a particular area determines the availability of arterialized skin flaps, fasciocutaneous flaps, myocutaneous flaps, and other forms of composite flaps. Local flaps can be grouped regionally by the types of tissue that they provide.

A local flap is generally preferred over a free flap if the two provide similar tissue, primarily because of the additional effort required to transfer a free flap. A free flap procedure commonly takes twice as long as a local flap procedure.

Free flaps are indicated in areas where local flaps are unavailable (e.g., the distal third of the leg) or when an extremely large flap is needed but cannot be obtained locally. When regional donor sites are affected by the primary process, free tissue transfer allows healthy, well-vascularized tissue to be brought into the compromised area. Moreover, if free tissue is transferred, the size of the wound is not extended, because the donor site is not contiguous but instead is located at a distance from the wound.

If expertise in microvascular surgery is available, free flaps are frequently a first-line choice. Free flaps allow selection of the appropriate type of tissue in the most suitable size and configuration for the specific reconstructive problem. Compared with free flaps, local flaps are inefficient ways of moving tissue because only a small portion of a local flap actually reaches the defect itself. The choice of donor site is greater with free flaps because the limitations imposed by local availability are avoided.

REGIONAL ALTERNATIVES IN FLAP SELECTION

Head and neck

Facial defects of small to moderate size are best treated with local skin flaps. A variety of flaps are available for reconstruction of limited defects of the eyelids, cheeks, nose, and mouth.^{16–18} Small

facial defects that do not directly involve the facial features can often be closed with any of several types of flaps that rearrange the existing tissue in the area—for example, a Z-plasty or a Limberg flap. Tissues that are difficult to match (e.g., those of the eyelids or lips) can often be reconstructed with flaps that borrow tissue from their opposite, intact counterparts (e.g., the Abbe lip flap).

For coverage of some large defects in the head and neck region, the trapezius, the latissimus dorsi, and the pectoralis major can be used. Each muscle can be raised with an optional skin island. These flaps are generally too bulky to be used on the face, and their reach is limited when used as pedicled flaps. None of them can cover major portions of the scalp or comfortably reach the upper face.

Latissimus dorsi, scapular, and rectus abdominis free flaps are useful for very large defects of the scalp or upper face. Smaller defects of the scalp are best treated with local scalp flaps.

Other free flaps of a specialized nature are superior for reconstruction of the floor of the mouth and mandible, even though local myocutaneous flaps will reach this area. For example, the forearm free flap based on the radial artery is quite thin and pliable and therefore provides an ideal replacement for the floor of the mouth. Composite free flaps that contain both bone and skin (e.g., those taken from the scapula, the ilium, the radius, and the fibula) provide tissue of the appropriate type and proper configuration for defects of the lower face in which the mandible must be reconstructed along with the intraoral lining, the external skin, or both.

Chest and back

Most clean defects of the chest and back are amenable to treatment with local myocutaneous flaps because of the wide arc of rotation of muscles located in these areas.¹⁹ In the presence of contamination,

open wound management is indicated. Traditionally, this has been accomplished with wet-to-dry dressing changes, which are especially effective for superficial débridement. Currently, these wounds are increasingly being managed with NPWT after all necrotic tissue is débrided. A common example is the wound resulting from the treatment

of poststernotomy mediastinitis. After sepsis is eliminated and the wound is granulating, definitive flap closure can be performed.^{20,21} Midline sternal wounds can be covered with pectoralis major, rectus abdominis, or omental flaps; lateral chest defects with latissimus dorsi or pectoralis major flaps; and midline back defects with latissimus dorsi or trapezius flaps. To cover midline defects, the pectoralis major, the latissimus dorsi, and the trapezius can be divided from their primary vascular supply and folded over as local flaps based on their medial segmental intercostal secondary blood supply.

Arm and forearm

Large wounds above the elbow can be covered with a latissimus dorsi myocutaneous flap transposed as a pedicled flap, provided that the vascular pedicle of the muscle has not been affected by the injury.

Forearm wounds that require flap closure are best treated with free flaps. A rectus abdominis, scapular, anterolateral thigh, or latissimus dorsi muscle flap can be used for large defects of the arm or forearm. Although soft tissue coverage with simultaneous functional forearm muscle replacement can be achieved with a single flap (e.g., a gracilis muscle flap), this is generally reserved as a secondary operation. A skin flap (e.g., a scapular free flap) is preferred as a first stage of reconstruction to achieve wound healing.

Hand

Both free flaps and pedicled skin flaps are useful for soft tissue coverage of hand wounds. A temporalis fascia free flap is particularly thin and is ideal for coverage of exposed tendons on the dorsum of the hand. A lateral arm free flap is ideal for reconstruction of a large defect of the first web space; it has sensory potential because it contains a large sensory nerve. Both of these free flaps are small. Pedicled distant skin flaps from the chest or abdomen are available as an alternative form of coverage for sizable hand defects. However, pedicled skin flaps have major disadvantages: wound care is difficult, edema persists because elevation and movement of the hand are seldom possible while it is attached to the trunk, and a second procedure is needed to divide these flaps.

Digital injuries with exposed tendons can be closed with a variety of cross-finger flaps of skin and subcutaneous tissue raised from either the volar or extensor aspect of an adjacent digit. Because these flaps do not contain a great deal of subcutaneous tissue, they are preferred for coverage of digits proximally, where a thick subcutaneous pad is not essential. A thenar flap is useful for fingertip injuries in which the soft tissue pad of the fingertip is lost and bone is exposed. This

flap provides an ideal pulp replacement, as well as better sensory recovery than skin grafts. Fingertip injuries can also be closed with several types of -Y advancement flaps that can be raised from either the volar surface or the lateral surfaces of the end of the finger.

Abdomen

Clean defects of the abdominal wall that require flap closure are best treated with local muscle flaps such as the tensor fasciae latae and the rectus femoris from the thigh. The rectus abdominis also can occasionally be trans-

posed to cover an abdominal defect. Each of these flaps is harvested along with skin, although a large tensor fasciae latae flap will probably necessitate skin-graft closure of the donor site. The tensor fasciae latae flap has the advantage of including the thickened deep fascia (iliotibial band) of the thigh, which can provide additional strength for abdominal wall closure. Midline defects resulting from previous operation or trauma can often be closed by means of the component separation method. The external oblique fascia is divided lateral to the lateral edge of the rectus sheath, and the bloodless plane between the external and internal oblique muscles is developed. This maneuver mobilizes the recti toward the midline, usually allowing primary closure. Adding a prosthetic mesh reduces the recurrent rate of hernias but is more difficult to manage when exposed or infected.

As a consequence of the growing realization of the benefits of the open abdomen, increasing numbers of patients treated for abdominal trauma, sepsis, and compartment syndrome are presenting for management and closure. With contaminated wounds, the use of permanent meshes for reconstruction is contraindicated, and definitive flap closure is best delayed. In these difficult situations, the wound must be treated in an open manner, with close attention paid to the unique vulnerability of the intestines to fistula formation. Many treatment options are currently available for the open abdomen [see 7:6 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*]. Important considerations for any treatment modality include whether the method controls abdominal contents, whether it avoids promoting fistula formation, whether it achieves skin and fascial closure, whether it removes and quantifies exudate, whether it controls infection, and whether it promotes wound healing. The VAC device performs well with respect to all of these considerations, perhaps because of reverse tissue expansion and full-thickness wound contraction.^{22,23} Once all acute problems have been addressed and recovery is well under way, an absorbable mesh is commonly applied, followed by dressing changes or NPWT. To protect the underlying bowel, a layer of nonstick gauze should be applied before dressings or NPWT sponges. Once granulation is achieved, a skin graft can be placed. Chronic hernia formation is the rule and can generally be treated as a stable chronic ventral hernia provided that the wound is closed and free of infection.

Gluteal area and perineum

Local muscle flaps with or without skin are indicated for defects in the gluteal area or the perineum. Such flaps are preferable to large, random-pattern advancement skin flaps from the posterior thigh and thoracolumbar rotation skin flaps. The gluteus maximus, for example, can be used as a rotation flap, a -Y advancement flap, or a turnover flap in the treatment of pressure sores. As a turnover flap, it can be proximally or distally based, or it can be split along its longitudinal axis so that only a portion of it is used. Also useful for covering defects in the gluteal area and the perineum is the myofasciocutaneous gluteal thigh flap, which is a combination of a gluteus muscle flap and a fasciocutaneous flap from the posterior thigh that is supplied by an extension of the inferior gluteal artery. Because of its size and location, the gracilis muscle is well suited for coverage of defects of the perineum. The gracilis and the biceps femoris are generally secondary choices for the treatment of pressure sores over the ischium. The tensor fasciae latae is frequently used for treating open wounds over the greater trochanter. The entire quadriceps can be used to close defects resulting from hemipelvectomy.

Thigh

Flaps are rarely required for soft tissue coverage in the thigh area because critical vital structures are located deep within the thigh and are rarely exposed by injury or by surgical procedures. A number of regional muscle flaps are available for coverage in this region, however, including the tensor fasciae latae, the rectus femoris, the vastus lateralis, and the vastus medialis. An anterior defect that involves exposure of the femoral vessels can be covered with a rectus abdominis myocutaneous flap, a rectus femoris flap divided distally and turned over, or a sartorius flap. The sartorius muscle has a segmental blood supply and will not be reliable if more than one to two segmental pedicles are ligated, which limits its utility for larger defects. A number of smaller local skin flaps that are supplied with blood from the deep fascia can be raised over portions of the thigh. The anterolateral thigh flap is the most commonly employed thigh flap for free tissue transfer.

Knee, proximal leg, and midleg

The two heads of the gastrocnemius can be used either together or independently to cover defects of the knee and the proximal third of the leg. The soleus is useful for coverage of defects of the proximal and middle thirds of the leg. Local flaps should not be used for major leg wounds if the extent of the injury suggests involvement of the muscle donor site. Instead, a free flap should be used to bring healthy tissue

into the area. Therefore, free flaps are a first choice, for example, for coverage of major wounds of the popliteal fossa, knee, and proximal leg that involve the sural artery blood supply to the gastrocnemius; they are also highly useful for coverage of defects in the distal third of the leg. Traumatic wounds of the distal lower extremity can also be managed with NPWT. Increased use of this modality has been associated with the performance of fewer free tissue transfers and more delayed local flap procedures for definitive closure.¹

Skin flaps fed by the fascial blood supply can also be raised over the leg.²⁴ A number of fasciocutaneous flaps have been described in this area, but they tend to be smaller than muscle flaps and generally less reliable. These flaps are longitudinally oriented over the course of the anterior tibial artery or the peroneal artery. The maximum length at which such fasciocutaneous flaps are safe and their specific applications have not been well established.

Foot

The foot is as complex as the hand and the face in that it is composed of separate regions, each of which has a unique set of alternatives for reconstruction. These regions include the plantar surface; the dorsum; and the posterior (non-weight-bearing) heel, Achilles tendon, and malleoli.

Superficial defects that lie completely within the non-weight-bearing portion of the midsole do not need flap coverage. Defects of the weight-bearing heel and midsole area that are less than 6 cm in diameter can be closed with a medially based skin rotation flap that is raised superficial to the plantar fascia.²⁵ This flap maintains plantar sensation. Limited defects of the distal plantar surface can be treated with local toe flaps that also maintain sensation. Very large plantar defects are best resurfaced with a muscle free flap (e.g., latissimus dorsi, gracilis, or rectus abdominis) covered with a skin graft or thin fasciocutaneous flaps. Although this type of flap lacks sensation, it appears to provide the most durable form of coverage because it resists shear forces well.²⁶

Defects of the dorsum that require flap coverage are best covered either with a fascial free flap (e.g., temporalis fascia) and an overlying skin graft or with a skin free flap that is thin (e.g., from the forearm or the anterolateral thigh). The extensor digitorum brevis can be raised from the dorsum as a pedicled flap fed by the dorsalis pedis artery. This flap, which measures approximately 5 × 6 cm, has an arc of rotation that makes it useful for the coverage of defects of the malleolus or the Achilles tendon area. A narrow transposition skin flap fed by the lateral calcaneal artery is useful for coverage of defects approximately 3 cm in diameter that lie over the Achilles tendon or the non-weight-bearing posterior heel. A distally based reverse sural artery flap transfers skin, subcutaneous fat, and fascia from the proximal posterior calf based on the vasa nervorum of the sural nerve, supplied by a distal branch of the peroneal at the level of the malleolus. This flap can also be used for defects of the ankle; however, it can be prone to venous congestion.

Secondary Reconstruction

Selection of the proper method for secondary reconstruction requires analysis of the type and extent of tissue deficiency that is present and consideration of the functional goals that are involved. Superficial defects may require replacement or supplementation of only skin and subcutaneous tissue, whereas more complex defects may require replacement of several types of tissue. Specialized tissue, such as vascularized nerve or intestine, may be necessary to provide a functional reconstruction in some cases (see below).

SMALL LOCALIZED SCAR

When reconstruction is indicated for a small localized scar, soft tissue coverage is generally sufficient and poses no threat of breakdown leading to exposure of important structures. Instead, the reconstructive problem is generally functional in nature. An example is a tight scar band across a flexion crease, which is commonly seen after a burn injury. A local procedure that rearranges the existing tissue can relieve the tension by making more tissue available in one direction, although the amount of tissue in the area is not actually increased.

The Z-plasty is an example of such tissue rearrangement. Multiple Z-plasties or other procedures, such as W-plasty, may be useful for some localized scars.

SHORTAGE OF SKIN AND SUBCUTANEOUS TISSUE

A shortage of skin and subcutaneous tissue may result from excision of a large scar or a large congenital defect (e.g., a nevus). Mastectomy commonly leaves a shortage of skin that prevents creation of a breast mound. In these cases, extra tissue can be created locally with the use of tissue expanders. These devices are inflatable plastic reservoirs of various shapes and volumes that are implanted under the skin. The skin over the expander is stretched during a period of several weeks as the expander is gradually filled by percutaneously injecting saline into an incorporated or remote fill port. The expander is then removed as a second procedure, and the expanded area of skin is advanced to cover the defect. The process of tissue expansion results in thinning of all layers of tissue overlying the expander—except for the epidermis, which actually thickens.

A number of important principles govern the use of tissue expanders. The expanders must be placed so as to allow expansion only in normal skin adjacent to the defect, not in the defect itself. To ensure adequate expansion, a sufficiently large expander or multiple expanders must be used. Complications associated with the use of tissue expanders include

infection, extrusion, deflation, flipped ports (remote type), and hematoma formation.²⁷

Tissue expanders are used in secondary reconstruction only; they play no role in acute wound management. They are not indicated for contour defects (see below), because the tissue they provide is two-dimensional and lacking in bulk. Expanded tissue may not be adequate for coverage of chronically exposed structures (e.g., bone).

The scalp is an ideal location for the use of tissue expanders because no equivalent substitute for this type of hair-bearing tissue exists. Expanders work effectively when implanted over the hard calvarium and are useful in cases of burn alopecia and large nevi involving the scalp. Expanders are also useful for breast reconstruction, for carefully selected large lesions of the face, and for certain scars of the limbs. They are generally not indicated for use in the hands or feet. Although some local flap donor sites (e.g., the forehead) can be expanded before flap transfer, there is a loss of tissue pliability that appears to limit the usefulness of this particular application.

COMPLEX DEFECTS

Certain reconstructive problems require substantial amounts of tissue of one or more types or of a very specialized type. Either local or free flaps are used to meet these tissue requirements.

Composite Defect

A composite defect may result from resection of an intraoral carcinoma with loss of the mandible and either the lining of the mouth or external skin. Another example is a crush injury of the leg with loss of soft tissue and a segment of weight-bearing bone. These defects require that a composite flap be brought to the area to meet more than one type of tissue deficiency. Local flaps generally do not provide the necessary types of tissue or permit the freedom of design possible with free flaps. The wide variety of free flap donor sites that exists allows selection of tissue in the appropriate quantity and configuration for a particular defect [see Figure 14].

Functional Defect

Functional defects require repair with specialized flaps. Free flaps are frequently used because the specific tissue requirements usually cannot be satisfied by a local flap. A functional defect may result, for example, in the cervical esophagus from tumor resection or in the forearm from the Volkmann contracture. A segment of small intestine can repair the esophageal defect; transfer of a vascularized and innervated muscle (e.g., the gracilis) can replace forearm muscle.²⁸

Contour Defect

Contour defects, such as those that result from mastectomy or from trauma to the lower extremity, can be reconstructed with either local or free flaps. A mastectomy defect, because of its location on the chest, is suitable for reconstruction with

Figure 14 (a) A chronic draining sinus of the ulna with poor overlying soft tissue coverage is shown. Simultaneous replacement of both bone and overlying soft tissue with a composite tissue flap is needed. (b) A radiograph shows nonunion of the ulna with orthopedic hardware. (c) A fibular free flap provides bone and skin in the appropriate amount and configuration for replacement of the affected tissues in a single stage. (d) The segment of ulna and overlying skin has been replaced. (e) A radiograph shows the vascularized fibula in place.

one of several myocutaneous flaps from either the back or the abdomen [see 3:5 *Breast Procedures*]. A free flap from the abdomen or the gluteal area is another alternative. The best reconstructive solution for a particular person is determined by variables such as body habitus and the size and configuration of the contralateral breast.

A contour defect of the lower extremity is best reconstructed with a large myocutaneous free flap that provides tissue of sufficient quantity and flexibility to allow sculpting into the appropriate shape. An excellent example is the latissimus

dorsi free flap, which provides a large volume of thin, pliable muscle, which can be wrapped around orthopedic hardware.

Unstable Soft Tissue Coverage

Marginal soft tissue coverage (e.g., skin grafts) may break down after repeated minor trauma. Bones may become exposed and are then at risk for osteomyelitis. This situation can be avoided by elective replacement of the tissue at risk with a more substantial soft tissue covering. As in acute reconstruction, local flaps are the first choice for lesions of the

trunk or the proximal extremities, whereas free flaps are often more appropriate for lesions of the distal extremities.

Soft tissue coverage is sometimes inadequate even in a healed wound. For example, certain procedures (e.g., nerve or bone grafting) require an ideal soft tissue bed to promote adequate graft revascularization. In some cases, it may initially be necessary to replace the existing soft tissue coverage as a first-stage procedure before grafting a bone or nerve gap. A skin or muscle flap is most commonly used in such cases. Muscle flaps tend to provide superior vascularity (e.g., for bone grafts) but are considered inferior for coverage of tendons that need to glide. This problem is most common in areas such as the distal extremities, where native soft tissue coverage is not overly abundant and is easily lost as a consequence of trauma or tumor resection. Free flaps are usually chosen to provide a healthy, well-vascularized soft tissue bed before further functional reconstruction is undertaken.

POST OPERATIVE CARE AND FLAP MONITORING

Local Flaps

The postoperative care of local flaps is not complex. Flap healing is supported by adequate nutrition and maintenance of a normal hemodynamic state, including normal blood volume. Tension must not be placed on the flap. Tension can develop in flaps on the trunk as a result of changes in patient position or in flaps on the limbs as a result of loss of immobilization. Generally, the tip of any local flap is not only its most valuable portion but also its most vulnerable area. At the tip, the blood supply is the most precarious, and the detrimental effects of tension are magnified. Unfortunately, no pharmacologic agents are of proven benefit in preventing necrosis of a flap with failing circulation. Any flap necrosis that might develop should be minimized by preventing infection of the necrotic tissue. Necrotic tissue must therefore be debrided after the extent of tissue loss becomes clear. Portions of the flap that are undergoing demarcation but do not appear actively infected can be protected by the application of a topical antibiotic (e.g., silver sulfadiazine cream).

Extremities that are recipient sites for flaps, such as those that are recipient sites for skin grafts, should be immobilized and elevated after the operation until satisfactory wound healing has occurred.

Free Flaps

Survival of free flaps, unlike that of local flaps, tends to be an all-or-none phenomenon. Careful postoperative monitoring of flap circulation is essential because flap failure is likely to be the result of a problem at the vascular anastomoses. Flaps are usually monitored for 7 days. However, the most critical time for free flap monitoring is the first 48 hours because the majority of vascular crises usually occur within this period. Early detection and aggressive investigation of such crises generally allow a flap to be salvaged. Maintenance of normal blood volume, treatment of hypothermia, and avoidance of pressors are particularly important in the early postoperative period to prevent vascular spasm. Spasm causes flaps to appear pale and to exhibit a significant temperature drop. There is no cutoff for hemoglobin or transfusion that has proven beneficial for flap survival. It is

recommended that transfusion be reserved for when indicated by other patient factors.

Free flaps exhibit venous engorgement when placed in a dependent position up to several weeks postoperatively. Such engorgement is generally not dangerous, although patients with free flaps below the knee should be gradually mobilized in the same fashion as patients with skin grafts in this location by keeping the lower extremity elevated for at least 10 to 14 days.

Free flaps in the head and neck area require that the patient's head motion be restricted somewhat for the first few days to prevent kinking of the vascular pedicle. It is important that electrocardiographic leads and tracheostomy tube ties not compress the external jugular vein if it was used as a recipient vessel for anastomosis. If central lines are used after operation, they should be placed on the contralateral side of the neck to prevent thrombosis near the microvascular anastomosis.

Free flaps should be monitored on an hourly basis during the early postoperative period. Most free flaps include an exposed skin island, which facilitates evaluation of the flap circulation. The flap is observed for color and for capillary refill—the most important indicators of flap viability. A pale flap generally indicates arterial insufficiency; however, this is not always the case, because certain donor sites, such as the abdomen, are relatively light in color under normal circumstances, which means that a flap from one of these sites may appear pale while still having an adequate arterial supply. Mottling is an indicator of arterial insufficiency in these circumstances. Flaps with venous insufficiency are characteristically blue in color and exhibit rapid capillary refill. In such flaps, an increase in the pink/red color of the skin with brisk capillary refill often precedes the blue discoloration, and it is cause for concern when observed. Bleeding from the edges of a flap and swelling are common in the presence of venous hypertension.

If a skin island is exposed, Doppler ultrasonography should reveal the presence of a triphasic arterial pulse. The site of this pulse should be marked with a suture, staple, or permanent ink to facilitate monitoring by nursing staff. A trained ear can distinguish between triphasic, biphasic, and monophasic pulses, which (in that order) indicate increasing degrees of arterial compromise from arterial thrombosis or increasing venous hypertension. Sometimes a cutaneous venous signal can be found. The venous signal is a multiphasic “whooshing” sound that augments with flap compression and then reduces as the flap fills with blood again. It then returns to its baseline. The signal will also get cut off when the pedicle is compressed. The nontrained ear will not distinguish between static and a normal venous signal, so it is important to train the monitoring staff to assess the venous signal while performing flap or pedicle compressing maneuvers. When the flap is buried, monitoring becomes more difficult. Alternative methods of monitoring buried free flaps are being developed and are being used with increasing frequency. One example is the implantable Doppler monitor. This device is placed in direct contact with the artery or vein distal to the anastomosis to obtain a continuous Doppler signal.²⁹ These devices are useful for buried flaps, when cutaneous signals are not found, when a complicated microanastomosis has been performed, and for monitoring the flap during inseting. Too tight of a closure

will change the venous signal from a multiphasic signal with augmentation on flap compression to a more monophasic signal that does not augment. Tissue oximetry has also been developed to monitor flaps with an external skin island.³⁰ Using this device, a probe is placed on the skin island and attached to a monitor that measures overall tissue oximetry (arterial and venous). A baseline level is reached, and any significant fall below the baseline indicates vascular compromise. The flap can be monitored remotely via the Internet, and when the level falls below a preset point, the machine can notify personnel via a pager.

Surface temperature probes can also be used to monitor free flaps that have a skin island. One probe is placed on the flap and another on a nearby area to serve as a control. The flap surface temperature is generally about 1.0° to 2.5°C lower than the control temperature. A progressive widening of this temperature difference is ominous and calls for critical assessment of the flap circulation. The absolute temperature of the flap probe is also significant: a flap temperature higher than 32°C indicates healthy circulation, whereas a temperature between 30° and 32°C indicates marginal circulation and a temperature lower than 30°C often indicates a vascular problem. In a healthy flap, temperature fluctuations may be caused by a dislodged probe, an exogenous heat source (e.g., a lamp), cooling of one of the probes from an oxygen mist mask, or cleaning of the flap skin with alcohol (which results in a precipitous drop in skin temperature).

To confirm the presence of an anastomotic problem, flap circulation is assessed directly by a full-thickness puncture of the flap skin with a 20-, 22-, or 25-gauge needle. If flap circulation is healthy, a drop of bright red blood should appear at the puncture site within a few seconds, and another drop should appear each time the previous drop is wiped away by an alcohol swab. The failure of blood to appear or the delayed appearance of a clear, serous ooze instead of blood is an indication of arterial insufficiency. Vigorous, dark bleeding confirms a venous problem. Flaps that are pale as a result of vascular

spasm are difficult to assess because their bleeding response to needle puncture is poor despite intact anastomoses.

As a rule, clinical judgment of flap viability on the basis of all of these methods of flap monitoring will be highly predictive. If, however, some uncertainty exists, surgical exploration should be undertaken because the entire flap may be in jeopardy.

Free flaps without skin islands are more difficult to monitor accurately. Muscle flaps can be followed in much the same way as skin free flaps by inserting needle temperature probes directly into the muscle belly. A healthy muscle free flap is red in color and typically has a serous ooze between the interstices of the overlying meshed skin graft. A flap with an arterial problem quickly becomes dry and dark in appearance. A muscle flap with a venous problem becomes dark and engorged with blood and exhibits bleeding from its surface and perimeter. A muscle free flap can be punctured with a needle to assess the quality of the bleeding if its circulatory status is unclear.

Fascial free flaps covered with skin grafts are also difficult to assess. They tend to transmit body core temperature readily because they are quite thin; therefore, needle temperature probes are generally unreliable. It is often possible in these cases either to observe the arterial pulsations in the flap directly or to monitor them with a conventional or implantable Doppler device.

Some free flaps are completely buried beneath the skin. Others, such as intraoral skin free flaps, are equally difficult to monitor postoperatively. Specialized transplants (e.g., jejunal transplants) are particularly vulnerable to short periods of anoxia and are not likely to be salvageable by the time a problem is recognized.

Financial Disclosures: None Reported.

4 SURGICAL MANAGEMENT OF MELANOMA AND OTHER SKIN CANCERS

Jennifer A. Wargo, MD, and Kenneth Tanabe, MD

The clinical assessment and management of skin lesions can be challenging as the natural history and prognosis of these lesions are widely variable. Surgeons play a pivotal role in the treatment of these lesions, although the initial evaluation of these lesions is often performed by other clinicians. The management of various benign skin lesions is beyond the scope of this review. Evaluation and management of malignant skin conditions are addressed in detail.

The prevalence of malignant skin lesions has increased significantly over the past several years. Approximately 1.2 million cases of nonmelanoma skin cancer are diagnosed per year.¹ More alarming, up to 80,000 cases of melanoma are diagnosed per year,² an incidence that has been rapidly increasing,³ with a lifetime risk of 1 in 75 for the development of melanoma.² The disturbing increase in the incidence of both nonmelanoma skin cancer and melanoma can largely be attributed to the social attitude toward sun exposure.⁴

Assessment of Skin Lesions

HISTORY AND PHYSICAL EXAMINATION

Obtaining a careful history is critical to the evaluation of skin lesions. Particular attention should be paid to a history of sun exposure. Blistering sunburn in childhood or adolescence is a significant risk factor and is present in virtually all Caucasians who develop melanoma.⁵ Patients should also be questioned about any personal or family history of skin cancer as those who report a history of melanoma in a first-degree relative have an 8- to 12-fold risk for the development of melanoma.⁶ In addition, patients should be questioned regarding immunosuppression and a history of transplantation as these put them at a higher risk of developing skin cancer.

A detailed history regarding when the lesion was first noted and changes in the size or the appearance of the lesion is important to elucidate. Generally speaking, lesions are nonsuspicious if they remain stable and uniform in their physical characteristics (e.g., size, shape, color, profile, and texture). An example of a nonsuspicious lesion is a simple nevus, which typically becomes apparent at 4 to 5 years of age, darkens with puberty, and fades in the seventh to eighth decades of life. However, pigmented lesions that demonstrate an irregular border or demonstrate a change in size, color, or texture

are considered to be suspicious. Careful attention should also be paid to constitutional symptoms as patients may present with advanced disease with metastases and systemic or focal complaints, such as headaches or visual changes in the case of melanoma metastatic to the brain.

Physical examination should include a complete skin examination and examination of mucous membranes. Specific attention should be paid to the presence of ulceration in a skin lesion as this significantly affects the prognosis depending on the histology of the lesion. Consideration should be paid to the potential draining nodal basins as lymph node metastases are known to occur in squamous cell cancer and melanoma.

Nonsuspicious lesions may be safely monitored conservatively with regular self-examination by patients and regular follow-up with their health care provider. Any change in a lesion constitutes a criterion for biopsy.

BIOPSY

Any suspicious lesion should be biopsied. This can be performed by excisional biopsy if the lesion is small or incisional biopsy if the lesion is large. Excisional biopsy should be performed incorporating a 1 to 4 mm margin of normal skin surrounding the lesion depending on the clinical characteristics. This may eliminate the need for subsequent reexcision for some types of lesions (e.g., dysplastic nevus). However, no attempt should be made to perform a definitive radical excision until a diagnosis is established by biopsy. Full-thickness excision into the subcutaneous fat should be performed, and margins on the specimen should be marked for orientation. This allows the pathologist to comment on the level of invasion and on margins for possible microscopic involvement with tumor cells. Electrocautery should generally not be used during excisional or incisional biopsy as margins can be distorted significantly by the artifact created by this technique. Shave biopsy for evaluation of pigmented lesions is discouraged as it runs the risk of a positive deep margin, which compromises the ability to determine the true depth of penetration of a melanoma or other malignant skin lesion.

The long axis of an elliptically shaped excisional biopsy should be oriented along the long axis of the extremity, which facilitates subsequent reexcision if necessary. If the lesion is

benign, no further treatment is warranted. If it proves to be malignant, further excision with an appropriate margin is usually necessary, and staging of the tumor becomes important. Adequacy of margins is discussed under each particular tumor type.

EXCISION

If a lesion proves to be malignant, complete excision should be performed with adequate margins as dictated by the type of tumor. An elliptical-shaped excision, with a length approximately 3.5 to 4 times the width, allows for a cosmetic closure without “dog ears.” If an area cannot be closed without significant tension, skin grafting may be necessary to achieve a technically acceptable result. Tissue transfer may also be required for very large lesions or for special areas, such as on the face.

Specific Types of Skin Cancer

BASAL CELL CARCINOMA

Incidence and Epidemiology

Basal cell carcinoma is the most common malignancy in Caucasians⁷ and the most prevalent type of skin cancer. The incidence is widely variable across the globe, with an incidence of 146 per 100,000 in the United States and 726 per 100,000 in Australia.⁸ The lifetime risk for a Caucasian in the United States for developing a basal cell carcinoma is approximately 30%.¹ Although the metastatic potential of these lesions is very low, the economic and social burden remains quite high.

In general, the vast majority of basal cell carcinomas occur on the head and neck. Basal cell carcinoma develops without a known precursor lesion, although it seems to be most closely related to exposure to ultraviolet radiation. Significant sun exposure during childhood and adolescence confers significant risk for the development of these lesions, although studies have failed to demonstrate a significant correlation between the development of basal cell carcinoma and cumulative exposure to ultraviolet light in adulthood.⁹ Several heritable conditions are associated with an increased risk of basal cell carcinoma, including albinism, xeroderma pigmentosum, and Gorlin syndrome. Patients with Gorlin syndrome develop multiple basal cell carcinomas, as well as anomalies of the spine and ribs, jaw cysts, pitting of the palms and soles, and calcification of the falx cerebri. Inheritance is autosomal dominant.¹⁰

Histologic Subtypes of Basal Cell Carcinoma

Several subtypes of basal cell carcinoma exist. Typical patterns seen in more mature lesions include nodular or cystic, superficial, morpheaform, and pigmented. Nodular or cystic basal cell carcinomas typically present as solitary lesions, often on the face, and are usually shiny and red, with central telangiectasias [see Figure 1a]. The classic basal cell carcinoma is the nodular type, which is also known as a “rodent ulcer.” These lesions are characterized by an indurated edge and an ulcerated center. Superficial basal cell carcinomas are typically found on the trunk and appear as an erythematous patch that is often mistaken for eczema or psoriasis and are typically slow-growing.¹⁰ Perhaps the most pertinent of these lesions is the morpheaform basal cell carcinoma [see Figure 1b], which

represents the minority of these lesions but has clinical features that are particularly pertinent to the surgeon. These lesions are often larger than they appear clinically and have a

Figure 1 (a) Typical basal cell carcinoma. A pearly luster and telangiectasias are evident in this typical basal cell carcinoma on the cheek of a 43-year-old man. (b) Morpheaform basal cell carcinoma. This sclerosing (morpheaform) basal cell carcinoma on the nose of a 55-year-old man was found to be deeply invasive and exhibited multidirectional growth.

more aggressive natural history, which can make complete excision quite challenging.

Treatment

Surgical excision remains the mainstay of treatment for primary basal cell carcinomas. Typically, a surgical margin of 4 mm is recommended when possible.¹¹ Primary closure is generally possible for small defects, and rotation flaps or skin grafting may be necessary for larger defects. Although present only extraordinarily rarely, lymphatic spread identified in the primary tumor may be an indication for lymphatic mapping.¹²

Other surgical techniques include cryosurgery, curettage and cautery, and Mohs micrographic surgery. Cryosurgery and curettage should generally be avoided in large or morpheiform tumors or in those in high-risk areas (such as the central face) as surgical margins cannot be assessed. Mohs micrographic surgery is a technique involving excision of serial sections with intraoperative histologic examination of frozen sections to control surgical margins. It is particularly useful in morpheiform or recurrent basal cell carcinomas or those in high-risk sites, with 5-year cure rates approaching 95%.¹³

Nonsurgical modalities available for treatment of basal cell carcinoma include radiotherapy, photodynamic therapy, and topical agents such as 5-fluorouracil, imiquimod, or intralesional interferon alfa. Radiation therapy is generally reserved for elderly patients with extensive lesions that preclude excision, with 5-year cure rates approaching 90%.¹⁴ Photodynamic therapy involves the use of -aminolevulinic acid in a 20% emulsion that is applied to the lesion followed by exposure to light in the wavelength range of 620 to 640 nm. This treatment is based on the uptake of the porphyrin metabolite by the tumor with subsequent conversion to protoporphyrin IX, which is subject to destruction in the presence of light.¹⁰ Responses to treatment are somewhat lower, with an overall clearance rate of 87% and a lower clearance rate of 53% in nodular basal cell carcinoma.¹⁵ Fluorouracil 5% cream may also be used in the management of multiple basal cell carcinomas of the trunk and limbs. Imiquimod is an immunomodulatory agent that is used in a 5% cream for basal cell carcinomas, with a clearance rate of 70 to 100%.¹⁶ Intralesional interferon alfa has also been used experimentally, with a 67% cure rate in a series of 140 patients treated in this manner.¹⁷

Patients who have been treated for any skin cancer, including basal cell carcinoma, should perform frequent self-examination to look for suspicious lesions as they are at a greater risk for developing additional skin cancers. Counseling to reduce sun exposure should be undertaken to limit further damage from ultraviolet irradiation. High-risk individuals, such as those with Gorlin syndrome or those who are on immunosuppressive therapy after renal transplantation, are offered oral retinoid treatment in the hope of preventing the development of other nonmelanoma skin cancers.¹⁷

SQUAMOUS CELL CARCINOMA

Incidence and Epidemiology

Squamous cell carcinoma of the skin is the second most common form of nonmelanoma skin cancer, with the majority (50 to 60%) of these lesions occurring on the head and neck. Squamous cell carcinoma is the most common tumor

found in elderly patients, likely representing the result of cumulative doses of sun exposure over the course of their lifetime.

Precursor Lesions

Unlike basal cell carcinomas, squamous cell skin cancers often arise in precursor lesions, such as actinic keratosis.¹⁸ Actinic keratoses, sometimes referred to as solar keratoses, develop in chronically sun-damaged areas of the body. They are generally ill-defined and irregular and may range significantly in size, from only a millimeter to a few centimeters. They have a scaly appearance, are often multiple, and can range in color from dark brown to flesh colored. Biopsy may be necessary to rule out the presence of a squamous cell carcinoma. The rate of malignant transformation of actinic keratosis to squamous cell carcinoma is less than 0.1% per year,¹⁹ although lesions should be treated to decrease the chance of progression. Treatment options include cryotherapy, curettage, and topical agents. Surgical excision of actinic keratoses is rarely necessary but may be indicated if there is a high suspicion for a concurrent squamous cell carcinoma.

Intraepithelial squamous cell carcinoma, carcinoma in situ, is thought to be the next step in the progression from actinic keratosis to invasive squamous cell carcinoma. Another term for this lesion is Bowen disease, and lesions are typically located on sun-exposed areas of the head, neck, trunk, or legs. This lesion is referred to as “erythroplasia of Queyrat” when located on the genitalia. When it occurs on non-sun-exposed areas, it may be associated with internal malignancy.²⁰ These lesions typically appear as erythematous, slightly keratotic plaques and are usually larger than lesions of actinic keratosis. These lesions should be excised with a 5 mm to 1 cm margin.

Diagnosis

Squamous cell carcinomas occur on the head and neck in approximately 50% of cases. Caucasians have nearly a 10% lifetime risk of developing a squamous cell carcinoma. Interestingly, in one series, nearly half of fatal cases of squamous cell carcinoma occurred in patients in whom the lesion arose from the ear.²¹ The mortality rate associated with squamous cell carcinoma is estimated at 1:100,000.²²

As noted, squamous cell carcinomas are most often associated with sun exposure, although they may also be seen in a background of old scars, radiation-damaged skin [see Figure 2a], or chronic open wounds.²³ Chronic inflammation and irritation appear to be the common denominators. Marjolin ulcer is a term for squamous cell carcinoma arising in a burn scar or open wounds such as osteomyelitis draining sites.

These lesions typically appear as keratotic papules, which may ulcerate, and may be reddish-brown, pink, or flesh colored [see Figure 2b]. A cutaneous “horn” may be evident if there is extensive hyperkeratosis.²¹ Symptoms that may suggest malignant transformation of actinic keratosis include pain, erythema, ulceration, or induration. Histologically, these lesions are characterized by nests of atypical keratinocytes that have invaded into the dermis, which may be well or poorly differentiated.

Once a diagnosis of squamous cell carcinoma is suspected, careful attention should be paid to the draining nodal basins

Figure 2 (a) Squamous cell carcinoma related to radiation exposure. This squamous cell carcinoma involving the thumb and index finger of a 72-year-old man, a retired dentist, was related to exposure to occupational hazards; he had subjected these digits to repeated radiation exposures by holding dental x-rays against his patients' teeth. (b) Squamous cell carcinoma related to sun exposure. This squamous cell carcinoma on the lip of a 70-year-old man was related to sun exposure; the patient was a nonsmoker.

as lymph node metastases are possible. Overall, the risk of metastasis is between 2 and 4% and is higher in larger, poorly differentiated lesions and lesions located on the scalp, nose, ear, lip, and extremities. The most common sites of metastasis are regional lymph nodes, the lungs, and the liver. Recurrence or metastases typically occur within 3 years after treatment of the index lesion.

Treatment

Surgical excision remains the mainstay of treatment for primary squamous cell carcinomas as well, although the recommended margin of excision is generally larger than that for basal cell carcinoma, ranging from 0.5 to 2 cm. Primary closure is often possible for smaller lesions, although larger lesions may require rotation flaps or skin grafting. Sentinel lymph node mapping should be considered for patients with large squamous cell carcinomas (e.g., > 2 cm) or those with histologic evidence of lymphovascular invasion. Fine-needle

aspiration of palpable nodal masses should be performed to diagnose metastatic squamous cell cancer, a condition that should be treated by aggressive lymphadenectomy. Adjuvant radiation therapy to the nodal basin is often indicated, based on the extent of nodal metastases.

Other therapies for squamous cell carcinoma are similar to those used to treat basal cell carcinoma and include cryosurgery, curettage and cautery, Mohs micrographic surgery, radiotherapy, photodynamic therapy, and topical agents such as 5-fluorouracil, imiquimod, or intralesional interferon alfa. Squamous cell carcinomas that develop from Marjolin ulcer are characterized by aggressive growth after surgical excision.

Patients who have been treated for squamous cell carcinoma should perform frequent self-examination to look for suspicious lesions as they are at risk for developing other non-melanoma skin cancers. Counselling to reduce sun exposure should be undertaken to limit further damage from ultraviolet irradiation. High-risk individuals, such as those who are on immunosuppressive therapy after renal transplantation, may be offered oral retinoid treatment in the hope of preventing the development of other nonmelanoma skin cancers.¹⁷

MELANOMA

Incidence and Epidemiology

Although it is less common than basal cell or squamous cell carcinoma, melanoma is clearly the most deadly of these cancers. Up to 80,000 cases of melanoma are diagnosed per year,² and it is the sixth leading cause of cancer death in the United States. The lifetime risk is estimated to be 1 in 75 individuals for the development of melanoma.² The incidence of melanoma is increasing significantly at a rate of 4.1% per year, faster than any other malignancy. The incidence is slightly higher in men than in women, and the median age at diagnosis is 57 years.²⁴ An average of 18.8 life-years are lost per melanoma death,²⁵ and it is estimated that one American will die from melanoma every hour.²⁶

Melanoma results from the malignant transformation of melanocytes, which are responsible for pigment production. Both genetic and environmental factors are implicated in the development of melanoma. Genetic susceptibility is important, and patients with melanoma often report a family history. Those who report a history of melanoma in a first-degree relative have an 8- to 12-fold risk for the development of melanoma.⁶ Somatic mutations in the *p16* tumor suppressor gene have been identified in both familial and sporadic cases of melanoma.²⁷ Environmental exposure to ultraviolet radiation also is implicated in the transformation of melanocytes. Risk for the development of melanoma is associated with intermittent, intense sun exposure rather than with a cumulative effect, although the exact mechanism behind the pathogenesis remains unknown.

In one study, six risk factors were identified by multivariate analysis to be important in the development of malignant melanoma and include the following: a family history of melanoma, a history of three or more blistering sunburns before age 20 years, the presence of blonde or red hair, the presence of actinic keratosis, a history of 3 or more years of an outdoor summer job as a teenager, and the presence of marked freckling on the upper part of the back.²⁸ Individuals with one or two of these factors have a 3.5-fold increased risk

Table 1 ABCD Guidelines for Pigmented Lesions	
Asymmetry	Most early lesions grow at an uneven rate, resulting in an asymmetrical pattern
Border irregularity	The uneven growth rate also results in an irregular border
Color variegation	Irregular growth also causes new shades of black and light and dark brown
Diameter	Lesions with ABC features and diameters of > 6 mm should be considered suspicious for melanoma

of developing melanoma, whereas if they have three or more, they have a 20-fold increase in risk.

Screening and Diagnosis

The frequency of screening of patients for melanoma should be based on the above risk factors. Routine screening of low-risk patients using a total body skin examination by health care providers is not supported. Self-screening, however, is clearly recommended, with excellent educational materials provided by the American Academy of Dermatology and the American Cancer Society. Nevertheless, physicians should take every opportunity to screen opportunistically as lesions found by physicians are significantly thinner than those detected by patients or their spouse.²⁹

Early recognition of melanoma is paramount to its effective treatment. The “ABCD” guidelines may be used in the evaluation of pigmented lesions [see Table 1].³⁰ These lesions often occur on sun-exposed areas of the upper trunk and extremities and are typically asymmetrical, with irregular borders and variegated pigmentation [see Figure 3a]. Occasionally, they lack pigmentation or are associated with significant ulceration. Any lesion suspicious for melanoma should be biopsied. Histologically, these lesions are characterized by atypical melanocytes with mitotic figures. Special staining may also be performed, and the most commonly used markers are HMB-45 and S100.

Histologic Subtypes

Melanoma may be further classified into histologic subtypes based on patterns of growth and anatomic location. The significance of these subtypes is generally less important than the pattern of growth (radial versus vertical growth) and depth of penetration.³¹ The most common subtypes include lentigo maligna melanoma, superficial spreading melanoma, acral lentiginous melanoma, and nodular melanoma. Superficial spreading accounts for over 70% of melanomas. These lesions are most common in white adults and typically occur on the back or legs. Nodular melanomas are the second most common, accounting for between 15 and 30% of all melanomas. These lesions often appear dome shaped and may occur anywhere on the body. They typically invade the dermis early in their natural history owing to an early vertical growth phase. Lentigo maligna melanoma accounts for approximately 5% of all melanomas and is thought to arise in a focus of lentigo maligna, or Hutchinson freckle. These lesions demonstrate a prolonged radial growth phase before developing an invasive component. Acral lentiginous melanomas occur on the hands or feet [see Figure 3b], often under the nail bed, where the

Figure 3 (a) Typical melanoma. A halo effect caused by loss of pigmentation is visible along the left margin of this melanoma on the upper back of a 33-year-old white woman; irregularities in shape, contour, and pigmentation are also evident. (b) Acral lentiginous melanoma. This melanoma, on the sole of the foot of a 47-year-old black woman, shows irregularities in shape, contour, and pigmentation.

dermis is thinner (e.g., subungual melanoma). A more rare histologic variant is desmoplastic melanoma, which typically occurs in areas of sun damage and tends more often to recur locally.

Prognostic Factors in Melanoma

An important variable in the prognosis of melanoma is the thickness of the primary tumor as assessed using the Clark or the Breslow system. The Clark system remains of primarily historical interest. In this staging system, levels I to V are defined by the presence of malignant melanocytes in each of the following layers: epidermis, papillary dermis, reticular dermis, and subcutaneous fat [see Figure 4 and Table 2].³² But the Breslow microstaging system has been demonstrated to have more prognostic information than the Clark system. Tumor thickness in the Breslow system is measured in millimeters from the epidermal surface to the deepest point of the tumor with a calibrated ocular micrometer [see Table 3].³³

Extensive research has been done over the past several years regarding prognostic factors in both early and late stage melanoma. Overall, clinical factors shown to have significant prognostic value include patient age, sex, location of the melanoma, number of involved lymph nodes, presence of distant metastasis, and serum lactate dehydrogenase (LDH) level.³⁴ Prognosis is generally better for patients < 65 years of age, women, tumor location on the extremities, absence of lymph node involvement, absence of distant metastasis, and a normal serum LDH level. The American Joint Committee of Cancer (AJCC) approved the latest version of the melanoma staging system in 2002, with changes that were validated via analysis of over 17,000 patients with melanoma [see Table 4].³⁴ Five-year survival rates correlate with stage [see Table 5].³⁴ A new version of staging will be released in 2009, incorporating additional factors such as mitotic rate³⁵ that influence prognosis and survival.

Table 2 Clark's Levels for Staging of Malignant Melanoma

Level		5 yr Survival Rate (%)
I	Malignant melanocytes are confined to the epidermis	99
II	Malignant melanocytes infiltrate the papillary dermis by single cells or small nests of cells	95
III	Malignant melanocytes fill and expand the papillary dermis with extension of the tumor to the papillary-reticular dermal interface (usually signifies vertical growth phase)	82
IV	Malignant melanocytes infiltrate the reticular dermis in a significant fashion	71
V	Malignant melanocytes infiltrate the subcutaneous fat	49

Table 3 Breslow's Microstages for Malignant Melanoma

Stage	5 yr Survival (%)
1: < 0.76 mm	> 98
2: 0.76–1.49 mm	87–94
3: 1.50–3.99 mm	66–83
4: > 4.0 mm	< 50

Stage I and II melanoma Those with localized melanoma represent the vast majority of patients, and several prognostic factors have been identified for risk stratification and prognosis in this heterogeneous group. The most important prognostic factors in early-stage melanoma are tumor thickness (T1 to T4) and the presence or absence of ulceration. These have significant

Figure 4 Clark categorized skin tumors according to their level of invasion. Tumors of level I involve the epidermis and are essentially carcinoma in situ. In level II, the tumor has extended into the papillary dermis. Tumor cells at level III are spread along the papillary-reticular dermal interface. Invasion into the reticular dermis occurs at level IV. Level V tumors extend into the subcutaneous tissue. In general, survival decreases as the depth of invasion increases.

Table 4 AJCC Staging of Malignant Melanoma

T classification		
T1	≤ 1.0 mm	A: without ulceration and Clark's level II or III B: with ulceration or Clark's level IV or V
T2	1.01–2.0 mm	A: without ulceration B: with ulceration
T3	2.01–4.0 mm	A: without ulceration B: with ulceration
T4	> 4.0 mm	A: without ulceration B: with ulceration
N classification		
N1	1 lymph node	A: micrometastases B: macrometastases
N2	2–3 lymph nodes	A: micrometastases B: macrometastases C: in-transit metastases, satellite(s) without metastatic nodes
N3	4 or more metastatic lymph nodes, matted lymph nodes, or combinations of in-transit metastases, satellites, or ulcerated melanoma and metastatic lymph node(s)	
M classification		
M1	Distant skin, subcutaneous or lymph node metastases	Normal LDH
M2	Lung metastases	Normal LDH
M3	All other visceral or any distant metastases	Normal LDH Elevated LDH with any M

AJCC = American Joint Committee on Cancer; LDH = lactate dehydrogenase.

Stage 0: Tis, N0, M0; stage IA: T1a, N0, M0; stage IB: T1b, N0, M0; T2a, N0, M0; stage IIA: T2b, N0, M0; T3a, N0, M0; stage IIB: T3b, N0, M0; T4a, N0, M0; stage IIC: T4b, N0, M0; stage IIIA: any T1–4a, N1b, M0; stage IIIB: any T1–4a, N2b, M0; stage IIIC: any T, N2c, M0; any T, N3, M0; stage IV: any T, any N, M1–3.

implications in prognosis as 5-year survival in stage I to II melanomas falls significantly with increasing thickness and dropped from 80% to 55% in the presence of ulceration in a 2006 analysis.³¹ Mitotic rate in the primary tumor has been identified as an important prognostic factor, possibly even surpassing ulceration in importance in early-stage melanoma.^{34,36} The mitotic rate will be incorporated into the new version of the AJCC staging system, which will be released in 2009.

Thin (< 1 mm thick) melanomas in particular have also been studied with great interest because they represent the largest group of patients. A recent publication from the University of Pennsylvania describes a prognostic model using four factors based on multivariate analysis: mitotic rate (0 versus ≥ 1), growth phase (radial or vertical), gender, and tumor-infiltrating lymphocytes.³⁷ Investigators developed an algorithm for risk stratification based on these factors, with minimal- and low-risk patients having a predicted risk for metastasis of less than 4%, whereas those who were considered moderate or high risk had a predicted risk for metastasis of 12 and 30%, respectively.³⁷

Intermediate-thickness (1.0 to 4 mm) melanomas clearly have a worse prognosis, with 5-year survival rates of 89% for nonulcerated T2 lesions (1 to 2 mm) and 77.4% for ulcerated lesions. Patients with ulcerated T3 lesions (2 to 4 mm) have

a predicted 5-year survival of 78.7% for nonulcerated lesions and 63% for ulcerated lesions. Thick (> 4 mm) lesions in node-negative patients have an associated 5-year survival of 67.4%, which drops to 45.1% if the lesion is ulcerated.³⁴

Stage III melanoma Stage III melanoma is characterized by the presence of nodal metastases (micro- or macro-metastases) with or without in-transit or satellite lesions. The presence of lymph node metastases confers a significantly worse prognosis, with less than half of node-positive patients surviving 5 years.³⁴ The number of involved nodes is also of prognostic significance and is reflected in the recent revisions to the AJCC staging system.

In patients with stage III disease, four prognostic factors for survival were identified: number of metastatic lymph nodes, microscopic versus macroscopic tumor deposits in lymph nodes, the presence of in-transit or satellite metastases, and the presence of ulceration in the primary lesion.³⁴ In earlier staging systems, the size of the involved lymph node was thought to be of significance, although this has been disproven.³⁸ However, macroscopic disease (that which is identified clinically and confirmed histologically) does have a significant impact, with a much poorer survival in those with macroscopic as opposed to microscopic disease.³⁴

Table 5 5-Year Survival Rates Based on AJCC Stage

Stage	T, N, M	5 yr Survival (%)
IA	T1a, N0, M0	95.3
IB	T1b, N0, M0	90.9
	T2a, N0, M0	89.0
IIA	T2b, N0, M0	77.4
	T3a, N0, M0	78.7
IIB	T3b, N0, M0	63.0
	T4a, N0, M0	67.4
IIC	T4b, N0, M0	45.1
IIIA	Any T, N1a, M0 (no ulceration, 1 node, micrometastases)	69.5
	N2a, M0 (no ulceration, 2–3 nodes, micrometastases)	63.3
IIIB	N1a, M0 (+ ulceration, 1 node, micrometastases)	52.8
	N2a, M0 (+ ulceration, 2–3 nodes, micrometastases)	49.6
	N1b, M0 (no ulceration, 1 node, macrometastases)	59.0
	N2b, M0 (no ulceration, 2–3 nodes, macrometastases)	46.3
IIIC	N1b, M0 (+ ulceration, 1 node, macrometastases)	29.0
	N2b, M0 (+ ulceration, 2–3 nodes, macrometastases)	24.0
	N3, M0 (+ ulceration, > 4 nodes, micro- or macrometastases)	26.7
IV	Any T, any N, M1a (skin or subcutaneous metastases)	18.8
	Any T, any N, M1b (lung metastases)	6.7
	Any T, any N, M1c (other visceral metastases + LDH)	9.5

AJCC = American Joint Committee on Cancer; LDH = lactate dehydrogenase.

In-transit and satellite metastases represent dissemination of tumor via lymphatic channels, and the 5-year survival rate in patients with these findings is similar to that of those with lymph node metastases. If these findings are present in association with lymph node metastases (N3), the survival rate drops significantly.³⁴

Stage IV melanoma For stage IV melanoma, the site of distant metastasis and serum LDH seem to have the most value in prognosis, with a far more favorable prognosis in those with cutaneous metastases and a normal serum LDH. On analysis, there is a significant difference in 1-year survival rates between those with cutaneous, subcutaneous, or distant nodal metastases (M1) versus those with lung metastases (M2) versus those with any other visceral metastases, or any metastasis with an elevated serum LDH (M3). Predicted 1-year survival rates for patients in these groups are 59%, 57%, and 41%, respectively.³⁴

Initial Evaluation

Recommendations for initial evaluation of patients with melanoma are as follows: all patients should receive a complete

history and physical examination, as well as a comprehensive dermatologic examination. For patients with thin melanomas (< 1.0 mm) or intermediate-thickness melanomas, no routine laboratory or radiologic tests are recommended. Chest radiography is considered optional in patients with stage IB or stage II melanoma as this is unlikely to pick up occult metastatic disease. For patients with stage III disease who present with clinically positive nodes, computed tomography (CT) of the chest, abdomen, and pelvis may be performed to confirm the presence of regional disease and to exclude the possibility of metastatic disease. In a patient with stage III disease defined by a microscopically positive sentinel node, the yield of CT scans is much lower, although current guidelines leave it to the discretion of the treating physician. If inguinal lymphadenopathy is apparent, pelvic CT should be obtained to assess iliac lymph nodes.³⁹ For patients with stage IV disease, a chest radiograph and serum LDH should be obtained. Brain magnetic resonance imaging and CT of the chest, abdomen, and pelvis should be performed before embarking on any surgery. Other imaging will be guided by protocol if the patient is enrolled in a clinical trial.³⁹

Surgical Treatment of Stage I and II Melanoma

Margins of excision Surgical excision remains the mainstay of treatment for melanoma. The width of the recommended surgical margins depends on the thickness of the lesion and has been well defined by a series of prospective randomized clinical trials. The most recent recommendations suggest that a 0.5 cm margin is adequate for in situ melanoma, whereas margins of 1 cm are suggested for melanomas less than 1.0 mm in thickness. Two-centimeter margins should be obtained for lesions measuring 1 to 2 mm in depth. Although a reduction in surgical margin width to 1 cm for melanomas 1 to 2 mm in thickness may slightly increase the risk for local recurrence, it would not reduce overall survival statistics. Two-centimeter margins should be obtained for melanomas greater than 2 mm in thickness.⁴⁰

Sentinel lymph node biopsy Another important issue in the surgical management of melanoma is the use of sentinel lymph node biopsy (SLNB), which has essentially replaced elective lymph node dissection. Sentinel lymph node status is the single most important predictor of survival in patients with melanoma⁴¹ and is considered a standard approach in this country. SLNB is recommended for intermediate-thickness (1 to 4 mm) and thick (> 4 mm) melanomas. It is generally not recommended for thin melanomas (< 1 mm) unless the lesion is of high risk (presence of ulceration, extensive regression, high mitotic rate, Clark level IV, or positive deep margin) or depending on the patient's age (SLNB may be performed in young patients). A positive result is defined as the presence of identifiable melanoma cells on either routine hematoxylin-eosin stains and/or by immunohistochemical staining with S100 or HMB-45. Preoperative lymphatic mapping via lymphoscintigraphy is very helpful in these patients as many lesions have variable drainage basins that cannot be predicted clinically and may even drain to contralateral nodes.⁴² The greatest accuracy is achieved when both radioactive colloid and blue dye are used during SLNB.⁴³ SLNB should not be performed in the setting of clinically positive nodes or in patients who would otherwise not be considered for lymphadenectomy.

The impact of SLNB for melanoma has been impressive. The results are critical to accurate staging and are also important in deciding whether to perform completion lymphadenectomy or offer adjuvant therapy. Several studies have demonstrated increased survival and disease-free interval between sentinel lymph node–negative and –positive patients.^{44,45} One of these studies demonstrated a 3-year disease-free survival of 88.5% versus 55.8% in sentinel lymph node–negative versus –positive patients, with a 58.6% increase in disease-free survival if the SLNB was negative.⁴⁴

Surgical Treatment of Stage III Melanoma

Therapeutic lymph node dissection Therapeutic lymph node dissection is currently recommended for management of the regional lymph node drainage basin in the presence of a positive sentinel node and in clinical stage III disease. Some challenge this recommendation as four randomized trials of elective lymph node dissection failed to demonstrate an overall survival benefit.^{46–49} Yet the majority of patients in these studies did not have nodal disease; thus, the trials were not sufficiently powered to detect a small survival benefit.⁵⁰ Other trials have supported this practice, including the World Health Organization 14 trial, which on subgroup analysis demonstrated a significantly improved 5-year survival rate in patients with occult nodal metastases detected at elective lymph node dissection compared with patients who had delayed lymphadenectomy at the time when they developed palpable nodal metastases (48% versus 27%, respectively; $p = .04$).⁴⁸

Nonetheless, the impact of completion lymphadenectomy on overall survival is still a matter of debate. This has been further addressed since the advent of the use of SLNB in melanoma. The results of the first Multicenter Selective Lymphadenectomy Trial (MSLT-I) suggest that SLNB with immediate completion lymphadenectomy if the sentinel node is positive improves disease-free survival but not overall survival for these patients.⁵¹ In this trial, 1,973 patients were randomized in a 4:6 ratio to wide excision followed by nodal observation (WEO) or to wide excision plus lymphatic mapping and sentinel lymph node biopsy (LM/SLNB) with immediate completion lymphadenectomy if the sentinel node was positive for metastasis. The groups were comparable in regard to age, gender distribution, and location, thickness, and ulceration status of the lesion. Sentinel nodes were analyzed using hematoxylin-eosin stain and immunohistochemistry. Wound complications at the primary site were comparable, although surgical morbidity was significantly greater when the SLNB was followed by completion lymphadenectomy.⁵¹ A follow-up analysis presented at the American Society of Clinical Oncology in 2005 demonstrated a significant difference in 5-year disease-free survival (73% in WEO versus 78% in LM/SLNB); however, there was no difference in 5-year overall survival (86% in WEO versus 87% in LM/SLNB).⁵² Although there were suggestions based on the data that a survival benefit might be gained by LM/SLNB followed by completion lymph node dissection in the event of a positive node, their statistical analysis has been criticized.⁵³ The role of lymphadenectomy will be addressed further in the second Multicenter Selective Lymphadenectomy Trial (MSLT-II), which is designed to evaluate the therapeutic value of completion lymph node dissection versus SLNB alone in patients who have metastasis in the sentinel node.⁵²

An important factor in considering a therapeutic lymph node dissection following a positive SLNB is the likelihood of finding

metastases in the remaining nonsentinel nodes. This was addressed in a recent series of 658 patients, in which 90 (14%) were found to have a positive sentinel node, with 18 (20%) of that group having evidence of metastases in additional nonsentinel nodes.⁵⁴ The number of positive nodes clearly has an impact on prognosis and is included in the AJCC staging system.³⁴ This adds credence to the argument for therapeutic lymph node dissection following a positive SLNB.

Another aspect of this topic that is debated is the extent of lymph node dissection required. Investigators at the John Wayne Cancer Institute recently reviewed their experience with therapeutic lymph node dissection prior to the use of sentinel node biopsy, and concluded that the extent of lymph node dissection is more important with higher tumor burden and less important with a lower tumor burden.⁵⁵ Those with micrometastatic disease in a sentinel node and those with bulky nodal disease are clearly different, and the potential benefits of therapeutic lymph node dissection must be carefully weighed against the morbidity of the procedure.⁵⁶ The role of lymphadenectomy and adjuvant alpha 2B and its impact on survival was addressed in the Sunbelt Melanoma trial,⁵⁷ the results of which were updated at the annual meeting of the American Society of Clinical Oncology in May 2008 (published in abstract form only). In essence, there was no significant difference in disease-free or overall survival among patients randomized to completion lymphadenectomy versus completion lymphadenectomy with adjuvant high dose interferon. There is, however, clearly a role for therapeutic lymph node dissection in patients with bulky nodal disease, and it can be performed with minimal morbidity and good palliation.⁵⁸

Isolated limb perfusion Patients with in-transit metastases have an unfavorable prognosis. This reflects a disseminated stage of disease, with a 5-year survival rate of 25 to 30%. Surgical excision is the mainstay of therapy when the size and the number of lesions permit, although there is no formal recommendation regarding the extent of surgical margin. Amputation is rarely necessary.

Another therapeutic option for patients with extensive in-transit metastases in an extremity involves the use of isolated limb perfusion (ILP). This technique was introduced in 1958 and holds the advantage of achieving high regional concentrations of therapeutic agents while minimizing systemic side effects.⁵⁹ The arterial supply and venous drainage are isolated, and an oxygenated extracorporeal circuit is used to circulate chemotherapeutic agents for 1 to 1.5 hours. A tourniquet is also often used. Melphalan is typically used as a chemotherapeutic agent, and the limb temperature is typically elevated to 39 to 40°C.⁶⁰ In patients who have clinically positive nodes, therapeutic lymph node dissection is performed at the same setting just prior to limb perfusion. The response to isolated limb perfusion can be dramatic. Complete response with melphalan alone is 54%,⁶¹ which is increased to 91% with the addition of tumor necrosis factor.⁶² However, these responses are often short-lived, with recurrence rates of 50% within 1 to 1.5 years after limb perfusion.⁶³ Overall 5-year survival after ILP was 32% in a recent series.⁶³ Recurrences following ILP may be treated with excision, although repeat ILP has also been used with success in patients with extensive disease.⁶⁴

ILP can be very effective for in-transit metastases; however, it is time and resource consuming and can be quite toxic. One

alternative to this approach involves the use of normothermic isolated limb infusion (ILI),^{65,66} a technique in which the artery and vein are isolated percutaneously and the limb is isolated using a tourniquet. Melphalan is typically used as a chemotherapeutic agent. One major difference between the two (ILP versus ILI) is that in ILI, blood is circulated at a much lower rate in the isolated extremity and only for 30 minutes. In addition, a pump oxygenator is not used in ILI; thus, the isolated extremity becomes hypoxic, leading to acidosis. The largest series of ILI reports the use of this approach with melphalan and dactinomycin chemotherapy in 135 patients.⁶⁵ In this series, there was an overall response rate of 85%, with 41% achieving a complete response and 42% achieving a partial response.⁶⁵ No randomized controlled trials compare ILP with ILI, although the results from a single-institution prospective database were recently published, yielding a higher overall and complete response rate for ILP versus ILI (88% versus 44% and 57% versus 30%, respectively).⁶⁶

Adjuvant Therapy

Radiotherapy Radiotherapy has been used with some success in high-risk lesions following therapeutic lymph node dissection, demonstrating a decrease in local recurrence⁶⁷ and a modest survival benefit⁶⁸ compared with historical controls. This modality is typically employed in stage III disease in the setting of poor prognostic pathologic factors, including positive surgical margins, multiple positive nodes, extracapsular spread, or vascular or perineural involvement.⁶⁹

Chemotherapy Adjuvant therapy with interferon alfa 2b is associated with improvement in disease-free survival but is also associated with significant toxicity. In addition, it is unclear whether adjuvant therapy with interferon alfa 2b enhances overall survival. Although initial studies (Eastern Cooperative Oncology Group trial 1684) demonstrated prolongation of relapse-free interval and overall survival with 1 year of high-dose interferon alfa 2b,⁷⁰ a subsequent meta-analysis showed no overall survival benefit.⁷¹ Furthermore, nearly all patients experience adverse effects with interferon therapy, including fatigue, neutropenia, headache, fever, and chills.⁶⁸ Interferon alfa 2b is currently approved by the Food and Drug Administration for adjuvant treatment of stage IIB and stage III melanoma.

Melanoma vaccines Several experimental melanoma vaccines are currently being investigated for use in advanced-stage melanoma and use a variety of strategies to present melanoma antigens to host immune cells in an immunostimulatory context.⁷²⁻⁷⁴ Despite initial optimism, a recent review of the experience at the National Cancer Institute demonstrated a response rate of only 2.6% for cancer vaccines,⁷⁵ which was comparable to the results obtained by others. The authors concluded that this approach may still be viable but will require profound changes to improve the efficacy of these vaccines.

Treatment of Stage IV Melanoma

Metastasectomy A large body of literature supports resection of metastases from melanoma, with the following factors cited as predictive of improved survival: stage of the initial disease, disease-free interval after treatment of the primary melanoma, initial site of metastasis (e.g., visceral versus subcutaneous), extent of metastatic disease (single versus multiple sites), and ability to achieve complete resection.⁵⁸ This approach can be successful as a recent series reported a 5-year survival

rate of 29% following pulmonary metastasectomy and a median survival of 40 months compared with 13 months in those who were not eligible for resection.⁷⁶ Similar results have been demonstrated in metastasectomy for metastatic lesions to the gastrointestinal tract, with a series reporting a median survival of 47.5 months in patients in whom a complete resection was achieved.⁷⁷ This was in sharp contrast to the median survival of 4 weeks in those patients in whom complete resection could not be achieved.⁷⁷ The aforementioned factors are of critical importance in deciding whether to perform metastasectomy, and patient selection is key. To enhance patient selection for curative procedures, some recommend treating patients with a single-site asymptomatic metastasis with 2 to 3 months of chemotherapy prior to resection to assess for disease stabilization or the development of additional metastases.⁵⁸ If there is a response to treatment or disease stabilization with no evidence of further metastases, these authors proceed with resection.

Preoperative imaging is a critical part of the evaluation of a potential metastasectomy patient and may include the use of 18-fluorodeoxyglucose positron emission tomography (FDG-PET) to more accurately detect occult metastatic disease. A recent comparison of FDG-PET with conventional imaging in patients with stage IV melanoma demonstrated a sensitivity and a specificity of 76% and 87%, respectively, for conventional imaging compared with 79% and 87%, respectively, for FDG-PET.⁷⁸ Sensitivity and specificity for combined conventional imaging with FDG-PET were 88% and 91%, respectively.⁷⁸ As with any other modality, it is important to understand the limits of the technology to apply its use properly.

Another important indication for metastasectomy is palliation as the vast majority of patients with stage IV melanoma will not be candidates for metastasectomy for curative intent. The goal of a palliative procedure is to control identifiable symptoms caused by an advanced malignancy while minimizing morbidity.⁵⁸ Classic examples of palliative metastasectomy include resection of bleeding small bowel metastases, resection of ulcerated subcutaneous metastases, and resection of symptomatic brain metastases. A thorough discussion should be held between the surgeon, the patient, and the family to address the goals and expected outcomes and the potential morbidity of the procedure.

Chemotherapy Response rates following adjuvant chemotherapy in the treatment of malignant melanoma have been somewhat disappointing. Dacarbazine (DTIC) is the agent with the longest track record in the treatment of melanoma and offers marginal therapeutic benefit with moderate side effects.⁷⁹ Various combination regimens have been used and include BOLD (bleomycin, Oncovin [vincristine], lomustine [CCNU], and DTIC), CVT (cisplatin, vincristine, and DTIC), and CBDT (cisplatin, BCNU [carmustine], DTIC, and tamoxifen) with response rates ranging from 9 to 55%.⁷⁹ However, the responses are not durable. More recently, temozolamide (an oral alkylating agent) was studied in stage IV melanoma patients, with a modest prolongation of survival compared with DTIC and an acceptable side-effect profile.⁸⁰

Melanoma vaccines Several experimental melanoma vaccines have been used in patients with stage IV melanoma in the context of clinical trials,⁷²⁻⁷⁴ although the results have not been very encouraging. An extensive review of the use of vaccines in advanced cancer suggests that significant improvements must be made to increase vaccine efficacy.⁷⁵

Immunotherapy Perhaps the most promising area of investigation for the treatment of advanced melanoma is immunotherapy. Immunotherapy has a wide range of definitions but is generally considered a form of treatment based on the concept of modulating the immune system to achieve a therapeutic goal.⁸¹ Multiple modalities can be considered immunotherapy, including the use of monoclonal antibodies and interferon-based therapy, although the focus of this review highlights the use of interleukin-2 (IL-2) and adoptive cell transfer.

High-dose IL-2 has been used to treat melanoma, with response rates in early series ranging from 15 to 20%, with complete regression in about half of these patients.⁸² Moreover, in those who achieve a complete response, the result is often durable.⁸³ However, this regimen is noted to be quite toxic.

Another modality under active investigation involves the use of adoptive immunotherapy. Adoptive immunotherapy involves the use of activated cytotoxic T lymphocytes (CTLs) that are generated against particular tumor types. This approach can help break immunologic tolerance by allowing the selection of tumor-specific T lymphocytes that are capable of generating a strong immunologic response. These can be generated using specific tumor-associated antigens or by culture with tumor cells. The addition of nonmyeloablative lymphodepleting chemotherapy prior to autologous transfer of tumor-specific CTLs in conjunction with IL-2 administration results in rapid clonal expansion of tumor-specific T lymphocytes *in vivo*, which is associated with a significant clinical response.⁸⁴ More recently, transfer of a T cell receptor gene from a patient with a significant antitumor response conferred impressive T cell responses.⁸⁵

Despite some advances in therapy, the overall survival for patients with stage IV melanoma has not improved over the past 20 years. Overall 5-year survival is dismal at less than 5%, with a median survival of only 7.5 months. Hope likely lies in treatment of micrometastatic disease via targeted chemotherapy and immunotherapy.

Conclusions

The clinical assessment and management of skin lesions are challenging, and surgeons play a pivotal role in treatment of these lesions. Furthermore, the prevalence of malignant lesions of the skin has increased dramatically over the past several years, with nearly 1.2 million cases of nonmelanoma skin cancer diagnosed per year¹ and close to 80,000 cases of melanoma diagnosed per year.² Thus, it is critical for surgeons to have an astute awareness of these lesions, their workup, and their management.

Specific Procedures

SUPERFICIAL AND DEEP GROIN DISSECTIONS

The inguinal nodes drain the anterior and inferior abdominal wall, perineum, genitalia, hips, buttocks, and thighs. A superficial groin dissection removes the inguinal nodes, whereas a deep groin dissection additionally incorporates the iliac and obturator nodes. Palpable nodes can be marked on the patient before operation.

Superficial Groin Dissection

The patient is placed in a supine position on the operating table, with the hip slightly abducted and supported by a

pillow and with the hip and knee slightly flexed. A Foley catheter is inserted, and the patient is prepared and draped.

The femoral artery, anterior superior iliac spine, pubic tubercle, and femoral triangle apex are marked, and a diagonally oriented skin incision is planned. The incision courses from medial to the anterosuperior iliac spine down to the apex of the femoral triangle. An “S”-shaped incision is used to avoid crossing the thigh flexion crease at a right angle. This incision interferes least with the musculocutaneous and cutaneous vascular territories of the skin, minimizes ischemia to the skin flaps, and avoids a flexion contracture. Flaps are raised to identify the medial border of the sartorius muscle, the lateral border of the adductor longus muscle, and the external oblique fascia on the lower abdominal wall. Fat and nodal tissue are dissected off the external oblique aponeurosis, spermatic cord, and inguinal ligament and are reflected inferiorly [see Figure 5]. The fat and lymph nodes are then dissected from the femoral triangle starting medially at the lateral edge of the adductor longus and proceeding laterally [see Figure 6 and Figure 7]. The femoral vessels are left undisturbed. At the fossa ovalis, the saphenous vein is ligated and divided [see Figure 8]. It is also ligated and divided as it exits the femoral triangle distally. The specimen is then dissected free from the femoral nerve, usually sacrificing branches of the lateral femoral cutaneous nerve, thereby resulting in numbness of the anterolateral thigh. The Cloquet lymph nodes are located medial to the femoral vein

Figure 5 In a superficial groin dissection, the incision is deepened to include the deep muscular fascia.

Figure 6 As the superficial groin dissection proceeds, the investing fascia overlying the femoral nerve and vessels is removed.

Figure 7 The superficial groin dissection is continued at the same level on the lateral side.

under the inguinal ligament and resected. Following removal of the specimen, these nodes are dissected out and submitted as a separate specimen. If the Cloquet nodes contain melanoma, the risk for iliac nodes with melanoma is high, and a deep groin dissection should be performed.

Deep Groin Dissection

The iliac region is easily approached through a separate incision in the external oblique fascia, parallel to and above the inguinal ligament. The retroperitoneal space is further exposed by separating the internal oblique abdominal muscle fibers and incising the transversus abdominis and fascia transversalis. The deep circumflex iliac vessels are ligated, and blunt finger dissection separates the peritoneum from the retroperitoneal fat and nodes. Alternatively, the inguinal ligament may be divided to allow access to the retroperitoneal space, although reconstruction of the inguinal ligament can be challenging.

Retractors are inserted to widen the retroperitoneal space, and the peritoneum and the abdominal viscera are retracted superomedially. The chain of lymph nodes, areolar tissue, and adventitial tissues along the external iliac vessels is dissected; the dissection proceeds proximally to the origins of the internal iliac vessels (avoiding the ureter) and incorporates the nodes overlying the obturator foramen by removing the internal obturator fascia but carefully avoiding injury to the obturator nerve. The lymph node-bearing specimen is then removed as a unit, oriented, and labeled appropriately with sutures. The space medial to the femoral vein under the inguinal ligament is obliterated to prevent a hernia. The sartorius muscle is detached from the anterior superior iliac spine and the midportion of the inguinal ligament to cover the femoral vessels. The skin and the subcutaneous tissues are then closed in layers over a soft suction drain.

Specific details regarding SLNB are described in a separate ACS chapter [see III:6 Lymphatic Mapping and Sentinel Lymph Node Biopsy].

Financial Disclosures: None Reported.

Figure 8 The great saphenous vein is ligated and divided.

5 BREAST PROCEDURES

Angela Gucwa, MD, J. Garrett Harper, MD, and D. Scott Lind, MD

The procedures used to diagnose, stage, and treat breast disease are rapidly becoming less invasive and more cosmetically satisfying while remaining oncologically sound. In particular, percutaneous core biopsy has largely replaced excisional breast biopsy for both palpable and nonpalpable breast lesions and has proved to be an equally accurate, less invasive, and less costly means of pathologic diagnosis.¹ Moreover, in clinically appropriate patients, sentinel lymph node biopsy (SLNB) has proved to be an accurate method of staging the axilla that reduces the incidence of many of the complications associated with traditional axillary node dissection.² Furthermore, breast conservation has largely supplanted mastectomy for definitive surgical treatment of breast cancer; randomized trials continue to demonstrate equivalent survival rates for the two therapies.³ Even in those cases where mastectomy is either required or preferred, advances in reconstructive techniques have been made that yield significantly improved outcomes after breast reconstruction.⁴ Finally, in an effort to eliminate the need for open surgical treatment of breast cancer, various percutaneous extirpative and ablative local therapies have been developed and are being evaluated for potential use in managing breast cancer in carefully selected patients.⁵

A more minimally invasive approach to breast disease will depend to a substantial extent on the availability of accurate and efficient imaging modalities. Adeptness with such modalities is rapidly becoming an essential part of the general surgeon's skill set. In this chapter, we describe selected standard, novel, and investigational procedures employed in the diagnosis and management of breast disease. The application of these procedures is a dynamic process that is shaped both by technological advances and by physicians' evolving understanding of the biology of breast diseases.

Breast Ultrasonography

Breast ultrasonography can be useful for evaluating palpable breast masses or mammographically indeterminate lesions; for carrying out postoperative and oncologic follow-up; for guiding aspiration and biopsy of lesions; and for facilitating intraoperative tumor localization, margin assessment, placement of catheters for partial-breast irradiation, and investigational tumor-ablating techniques.

In the office, breast ultrasonography has become a useful adjunct to the clinical breast examination, particularly in patients with radiographically dense mammograms. It defines breast lesions more clearly than physical examination does and

thus can potentially reduce the number of unnecessary biopsies done for simple cysts or fibroglandular tissue presenting as a palpable nodularity. Whole-breast ultrasonography is not an effective screening tool and therefore should not be a substitute for annual mammography. The American College of Surgeons (ACS) and various surgical subspecialty organizations offer a multitude of courses, at varying skill levels, geared toward training general surgeons in the use of breast ultrasonography.

TECHNIQUE

Most real-time ultrasound imaging is performed with handheld probes generating frequencies between 7.5 and 12 MHz. The procedure is conducted with the patient supine, a pillow behind the shoulder, and the ipsilateral arm extended over the head for maximal spreading of the breast. Sonographic transmission gel is applied between the transducer and the skin to reduce air artifacts, and the transducer is pressed slightly against the skin to improve image quality. The selected breast area is imaged from the nipple outward in a radial pattern.

All lesions should be sonographically characterized with respect to margins, effect on adjacent tissue, internal echo pattern, compressibility, height to width ratio, and presence of shadowing versus posterior enhancement. Classically, simple cysts tend to be oval or lobulated, anechoic, and sharply demarginated; they typically demonstrate posterior enhancement. Benign solid lesions tend to be well circumscribed, hypoechoic, and wider than they are tall; they show homogeneous internal echoes and edge shadowing. Carcinomas are also hypoechoic masses, but they cross tissue planes and therefore tend to be taller than they are wide, with irregular borders; in addition, they can demonstrate heterogeneous interior patterns and broad acoustic shadowing [see *Figure 1*]. A lesion that has a single indeterminate characteristic on ultrasonography or that is clinically suspicious despite appearing benign on ultrasonography is an indication for core or open biopsy. Lesions should be characterized in at least two orthogonal planes, and the image should be saved for future reference.

Ductal Lavage

The majority of breast cancers originate from the epithelium of the mammary ducts. Originally developed to increase the cellular yield after nipple aspiration failed to obtain adequate sampling, ductal lavage is a method of recovering breast duct epithelial cells for cytologic analysis via a microcatheter that is inserted into the duct.⁶ Potential applications include

Figure 1 Breast ultrasonography. Shown are (a) a simple cyst that has smooth margins, is anechoic, and shows posterior enhancement; (b) a fibroadenoma that has smooth margins, is hypoechoic, and shows posterior shadowing; and (c) a mammary carcinoma that has irregular borders, is hypoechoic, and shows irregular posterior shadowing.

identifying high-risk women, predicting risk with molecular markers, monitoring the effectiveness of chemopreventive agents, and delivering drugs directly into the ducts. At present, however, ductal lavage remains investigational, and its predictive value and clinical utility await further definition.⁷

TECHNIQUE

The breast duct epithelium may be sampled by means of either nipple fluid aspiration or ductal lavage. For the aspiration of nipple fluid, a topical anesthetic is first applied to the nipple, followed by a mild scrub with a dekeratinizing gel. Suction is then applied to the nipple while the breast is gently massaged. Aspirated fluid is sent for analysis. In ductal lavage, the breast and nipple are similarly prepared. The nipple duct orifice that yields fluid spontaneously or as a result of suction is cannulated, the duct is irrigated with saline, and the effluent is collected for cytologic analysis. Cannulation of the duct is possible in the majority of women. Both nipple fluid aspiration and ductal lavage are generally well tolerated. The former is simpler and less expensive, but the latter retrieves more cells.⁸

Ductoscopy

Advances in endoscopic technology have allowed for visualization and biopsy of the mammary ducts, including those in more peripheral locations.⁹ Mammary ductoscopy is a procedure in which a 0.9 mm microendoscope is employed to visualize the lining of the ductal system directly. Previous studies have revealed ductoscopy to be safe for use in three main areas: (1) evaluation of patients with pathologic nipple discharge,¹⁰ (2) evaluation of high-risk patients, and (3) evaluation of breast cancer patients to determine the extent of intraductal disease and perhaps reduce the rate of positive margins. This is especially important in those patients with in situ disease and benign radiographic findings.¹¹ Current research is aimed at the use of ductoscopy-directed biopsy and ablation techniques. Perforation of the mammary duct is the most commonly reported complication; however, this appears to have minimal sequela. At present, this investigational technology is available at only a few centers, and further study will be required to determine its precise role in the evaluation and management of breast disease.

TECHNIQUE

Ductoscopy can be performed either in the office or in the operating room with minimal discomfort. Before the procedure, a nipple block is usually performed with topical lidocaine cream, supplemented (if necessary) by intradermal injection of 1% lidocaine around the nipple-areola complex or intraductal instillation of lidocaine (or both). The breast is massaged to promote expression of nipple aspirate fluid, which facilitates identification of a ductal orifice. The duct is then gently dilated, and the ductoscope is advanced with the help of insufflation under direct visualization. Most ducts with pathologic discharge can readily be identified and dilated sufficiently to allow passage of the ductoscope.¹² Under direct visualization, the ductoscope is advanced using saline insufflation. An outer air channel on the fiberscope permits instillation and collection of saline solution so that cells can be retrieved for ductal lavage.¹³ Intraductal lesions can be percutaneously localized under direct endoscopic visualization for subsequent biopsy; alternatively, they may be amenable to endoscopic cytologic brushing or to the newly described technique of intraductal breast biopsy.¹²

The procedure is usually well tolerated. It should be noted that duct excision is still regarded as standard practice for pathologic discharge, regardless of endoscopic findings.

Breast Biopsy

Cytologic or tissue diagnosis of a palpable breast mass may be obtained by means of fine-needle aspiration (FNA) biopsy, core-needle biopsy (CNB), or open incisional or excisional biopsy. Currently, most solid lesions are initially diagnosed by means of CNB, which is less invasive, less costly, and more expeditious than open biopsy while achieving comparable accuracy. In select circumstances, however, FNA biopsy and open biopsy may remain suitable options. All minimally invasive biopsy techniques are facilitated when guided by imaging modalities; such guidance enables the physician to perform a more directed biopsy that targets the lesion precisely while avoiding benign-appearing tissue, necrotic tissue, and adjacent structures (e.g., the chest wall, skin, and axillary vessels). Therefore, even when a lesion is palpable, ultrasound-directed

biopsy is preferable to blind biopsy (although not absolutely necessary) and is recommended if the surgeon has a suitable ultrasound device in the office.

The choice of a specific biopsy technique should be individualized on the basis of the clinical and radiographic features of the lesion, the experience of the clinician, and the patient's condition and preference.

FINE-NEEDLE ASPIRATION BIOPSY

FNA biopsy permits the sampling of cells from the breast or the axillary region for cytologic analysis. It is particularly useful for sampling a clinically or sonographically suspicious axillary node and for evaluating cyst fluid that is bloody or that comes from an incompletely collapsed or recurrent cyst. In patients receiving anticoagulants, FNA biopsy is a reasonable alternative to CNB for evaluation of a solid lesion in that there is less potential for hemorrhage if anticoagulation cannot be discontinued. Discrete masses discovered on physical examination may be either cystic or solid. A lesion that is shown by ultrasonography to be a simple cyst need not undergo FNA biopsy unless it is symptomatic.

Technique

The skin of the breast or axilla is prepared, and a local anesthetic is injected superficially via a 25-gauge needle. Although smaller needles may be used, a 21-gauge needle is optimal for FNA biopsy because it can be effectively used both for aspiration of potentially viscous fluid and for procurement of sufficient cellular material from solid masses. To generate adequate suction, a 10 mL or larger syringe should be used. As noted (see above), FNA biopsy ideally is performed under ultrasonographic guidance. If such guidance is unavailable, the lesion is held steady between the thumb and the index finger of the nondominant hand. Before the needle enters the skin, 1 mL of air is introduced into the biopsy syringe. Then, without the application of suction, the needle is advanced into the lesion. Once the needle is in place, strong suction is applied.

If the lesion is cystic, all fluid is aspirated, at which point the mass should disappear. Ultrasonography can confirm the complete collapse of a cyst or help direct the needle to an undrained portion of the cyst. The fluid need not be sent for analysis unless it is bloody or is associated with a residual palpable mass or an incompletely collapsed cyst as seen on ultrasonography. If the fluid is to be sent for analysis, it is injected directly into the pathologic preservative. The patient is reexamined 4 to 8 weeks after successful aspiration. If the same cyst has recurred, aspiration should be repeated and the new aspirate sent for cytologic analysis.

If the lesion is solid, the needle is moved back and forth within the lesion along a 5 to 10 mm tract until tissue is visualized in the hub of the needle. (This oscillation of the needle along the same tract is the most effective way of obtaining a cellular, diagnostic specimen.) Suction is released while the needle is still within the lesion, and the needle is then withdrawn. The contents of the needle are expelled onto prepared glass slides, spread into a thin smear, and fixed according to the preferences of the cytology laboratory. The syringe may be rinsed so that a cellblock can be prepared for further analysis. The lesion should be sampled twice to ensure that a sufficiently cellular sample has been obtained.

Interpretation of Results

Accurate interpretation of FNA requires substantial experience on the part of both the operator and the cytopathologist; only in a few select centers with expert breast cytopathologists has it remained the diagnostic procedure of choice for solid breast masses. Consequently, one must exercise considerable caution about using FNA biopsy rather than CNB as the sole means of confirming a cancer diagnosis before the initiation of definitive operative management or neoadjuvant therapy. FNA biopsy is unable to discriminate carcinoma in situ from invasive carcinoma and therefore is incapable of establishing whether axillary node staging is needed. Furthermore, because of the smaller quantity of tissue extracted, FNA biopsy is a less reliable means of assessing receptor status than CNB is. Finally, in 1 to 2% of cases, FNA biopsy may yield false positive results,¹⁴ potentially leading to an unnecessary cancer operation. For these reasons, it is recommended that malignancies identified by FNA biopsy be confirmed by means of CNB or open biopsy (preferably the former) before definitive therapy is provided.

Cytologic analysis that is diagnostic of a specific benign lesion (e.g., a fibroadenoma) may generally be relied on if it is in concordance with the clinical features of the lesion. However, a negative result from FNA biopsy does not exclude cancer: this procedure fails to diagnose as many as 40% of breast malignancies.¹⁴ Cellular atypia, pathologic discordance, or a nondiagnostic FNA is an indication for tissue diagnosis.

CORE-NEEDLE BIOPSY

As noted (see above), CNB is the diagnostic procedure of choice for breast lesions. Like FNA biopsy, it is easily performed in an outpatient setting. Unlike FNA biopsy, CNB removes a narrow cylinder of tissue that is submitted for pathologic rather than cytologic analysis. Whenever feasible, CNB of both palpable and nonpalpable lesions is performed under ultrasonographic guidance, which permits real-time documentation of the needle's position within the lesion. For lesions not visualized on ultrasonography or for suspicious microcalcifications, stereotactic guidance may be employed instead. A preoperative diagnosis of malignancy obtained via CNB enables the surgeon to perform a single-stage operative procedure. It may also help lower the positive margin rate for patients undergoing breast-conserving therapy (BCT), thereby reducing the need for reexcision and improving the cosmetic outcome.¹⁵

Various automatic, rotational, and vacuum-assisted devices may be employed to perform CNB; in what follows, we briefly discuss these devices [see *Technique, below*]. When CNB is performed with a 14-gauge needle, as is the case with Tru-Cut (Cardinal Health, Dublin, Ohio) devices and spring-loaded guns, up to 30% pathologic upgrading may be seen on subsequent surgical excision.¹ When CNB is done with a larger needle (8 to 11 gauge), as is the case with image-guided vacuum-assisted and rotational devices, a greater volume of tissue is delivered; consequently, less pathologic upgrading is seen.¹⁶ With the vacuum-assisted core biopsy (VACB) devices currently available, it is possible to remove all radiographic evidence of the lesion. It is therefore common practice with all core biopsies to place a titanium clip or another surrogate marker at the biopsy site to facilitate future localization procedures. In addition, a clip should be placed at the biopsy site if the patient has a larger

cancer for which neoadjuvant chemotherapy is required; some such lesions exhibit a complete clinical response to chemotherapy and thus are no longer radiographically visible at the time of definitive operative treatment. Two-view postbiopsy mammography should be performed to confirm accurate placement of the clip and adequate sampling of the lesion at the time of biopsy.

Technique

Palpation-guided biopsy In this setting, a manual Tru-Cut-type device or, more commonly, a spring-loaded semiautomatic biopsy gun is used to obtain the specimen. The skin is prepared, and a local anesthetic is infiltrated superficially via a 25-gauge needle. A nick is made in the skin with a No. 11 blade to permit easy entry of the biopsy needle (usually a 14-gauge needle). As with FNA biopsy (see above), the lesion is held steady in the nondominant hand while the biopsy needle is advanced into the periphery of the lesion. Next, the needle is manually advanced through the center of the lesion (if a manual device is used), or the gun is fired (if a spring-loaded device is used). Finally, the needle is withdrawn to retrieve the core. Four to five cores, each from a separate pass, should be obtained to ensure that the lesion is not undersampled. Pressure is applied over the lesion and the biopsy tract for 10 to 15 minutes to ensure adequate hemostasis. The nick in the skin is closed with an adhesive strip (e.g., Steri-Strip, 3M, St. Paul, Minnesota).

Ultrasound-guided biopsy This technique may be employed for both palpable and nonpalpable lesions. The lesion that is to undergo biopsy is centered on the screen of the ultrasound device. A local anesthetic is injected superficially, first along the anticipated biopsy tract and then both anterior and posterior to the lesion; this latter maneuver helps ensure that there is a safe distance between the lesion and the skin or the chest wall. A nick is made in the skin with a No. 11 blade. The biopsy needle is then inserted through the skin, with care taken to keep it in a plane parallel to the footplate of the ultrasound probe as it passes through the breast tissue. The biopsy itself can be either performed in a freehand manner or directed with a needle guide attached to the probe. The ideal final positions of the tip and shaft vary, depending on the particular biopsy device selected for the procedure [see Figure 2]. Regardless of which device is used, the tip and shaft of the needle should be visualized throughout the entire approach to and biopsy of the lesion. Prefire and postfire images should be obtained that show the needle in proximity to and within the lesion, respectively. Four to five good cores are required for adequate sampling. Once the biopsy is complete, pressure is applied over the lesion and the biopsy tract, and a Steri-Strip is placed. To facilitate closure of larger entry sites, a single subcuticular stitch may be used.

Brisk bleeding may occur during and immediately after the procedure, but it usually can be controlled by the application of direct pressure. Patients are restricted from engaging in strenuous activity for 24 hours after biopsy. Bruising may result, but it typically resolves within days. Other potential complications include hematoma, fat necrosis, a palpable lump, and infection; however, such events are uncommon. Most patients receiving oral anticoagulants can be switched to a subcutaneous alternative that can be stopped on the morning of the procedure.

Semiautomated gun biopsy When a spring-loaded semiautomatic biopsy gun is used, the tip of the needle should abut the lesion in such a way that the biopsy trough will be in the lesion after the device is fired. Ideally, the repeat passes should sample different portions of the lesion and avoid any necrotic areas that have been visualized.

Vacuum-assisted core biopsy Vacuum-assisted rotational cutting devices employ a 7- to 11-gauge probe with a distal sampling trough and an inner rotating cutter. The sampling trough can be placed either in the center of the lesion or directly under it. The probe is attached to a vacuum system, which draws the target tissue into the trough. Once the tissue has been drawn into the trough, the inner rotating cutter is advanced and cuts a core from it. The tissue core is then delivered by the vacuum system through the barrel of the probe and into a proximal collection chamber. The probe can be rotated up to 360° and can retrieve multiple samples through a single insertion in the skin. The larger tissue volumes obtained with these rotational VACB devices have reduced the incidence of atypical ductal hyperplasia or ductal carcinoma in situ (DCIS) upgrades on subsequent excisional biopsies.⁵

Cryoassisted core biopsy In a cryobiopsy, a thin (19-gauge) solid needle is placed in the middle of the targeted tissue. The tip is then cooled to approximately 10°C, a temperature that freezes the tissue to the needle but does not cause tissue necrosis. An outer rotating cutting cannula (10 gauge) is then advanced over the inner localizing needle. The device is removed from the breast, and the single specimen is removed. As with the semiautomatic biopsy gun, multiple passes into the breast are still required. However, the local anesthetic effect of the cooling process, the ability of the device to spear and stabilize a lesion, and the absence of a firing gun-type action make cryobiopsy advantageous, particularly for a mobile lesion that lies close to the skin or the chest wall.

Stereotactic-guided biopsy Lesions that are visible on mammography—including small solid lesions, asymmetrical densities, and suspicious groups of microcalcifications—can often be targeted and subjected to core biopsy under stereotactic guidance.¹⁷ Stereotaxy refers to the use of three-dimensional coordinates to localize and identify the lesion and determine the precise positioning of the tissue to be sampled.¹⁸ This outpatient procedure commonly makes use of a mounted VACB gun, similar to the handheld VACB device previously described (see above). Stereotactic biopsy is appropriate for lesions that are clearly visible on digital images and identifiable on stereotactic projections. Lesions that lie close to the chest wall or in the subareolar region may not be amenable to stereotactic biopsy and are often best approached via open biopsy with needle localization (see below). Likewise, lesions in thinly compressible breasts may not be amenable to stereotactic biopsy, because firing of the needle may result in a through-and-through injury to the breast. Certain stereotactic systems may not be suitable for patients who are unable to lie prone or are morbidly obese. It should be kept in mind that stereotactic biopsy is a diagnostic procedure and is not intended for therapeutic purposes. On the whole, it is safe, and the complication rate is acceptably low.

Depending on the system being employed, the patient either lies prone on the stereotactic table or sits upright. With the breast compressed craniocaudally or mediolaterally, stereotactic digital imaging is then performed to visualize the

Figure 2 Core-needle biopsy. The positioning of the needle shaft and tip varies with the particular biopsy device being used. (a) For manual or semiautomatic guns that fire through the lesion, the position of the tip before firing should be at the edge of the lesion. Keeping the needle shaft parallel to the chest wall or the skin keeps these structures from being injured when the gun is fired or the core is manually obtained. (b) For most vacuum-assisted devices, multiple cores can be obtained through a single placement of the device within the breast. For diagnostic biopsies performed under ultrasonographic or stereotactic guidance, the needle may be placed in the center of the lesion and rotated up to 360° in specified intervals. (c) For cryobiopsy, the tip of the needle should be advanced through the center of the lesion toward the far edge of the lesion before firing. This step stabilizes the lesion. The outer cutting and rotating cannula is then fired over the inner needle. VACB = vacuum-assisted core biopsy.

targeted lesion and calculate its location in three dimensions, and a suitable probe insertion site is identified. The skin is prepared, and a small amount of buffered 1% lidocaine with epinephrine is administered. The skin at the insertion site is punctured with a No. 11 blade, the probe is manually advanced to the prefire site, and the position of the probe is confirmed by means of stereotactic imaging. The device is then fired, repeatedly cutting, rotating, and retrieving samples until the desired amount has been removed. Targeted removal of suspicious microcalcifications is confirmed with specimen mammography.

Once the biopsy is complete, an inert metallic clip is deployed into the biopsy site through the probe for future localization; deployment and positioning are initially confirmed by

stereotactic imaging. The biopsy device is then removed, the edges of the skin incision are approximated with Steri-Strips, and a compressive bandage is applied. Typically, 1 g of tissue (equivalent to approximately 10 to 12 samples with an 11-gauge probe) is sufficient for diagnosis. Once the procedure is over and the breast has been released from compression, a two-view mammography should be obtained to verify that the clip was accurately placed and to document that the targeted lesion was adequately sampled.

Magnetic resonance imaging-guided biopsy Contrast-enhanced magnetic resonance imaging (MRI) has been found to be a highly sensitive method for detecting breast cancer, especially those that are nonpalpable or are unable to be viewed using conventional radiographic methods. A stereotactic method similar to the one described above has been developed using a VACB to perform an incisional biopsy under MRI guidance. Similarly, the patient is placed prone and the targeted breast undergoes mediolateral compression. Using MRI, a software program calculates the three-dimensional coordinates for the biopsy device. The VACB gun is used outside the magnet, so MRI compatibility is not required. After several tissue samples are removed, the resulting cavity is directly visualized to ensure precise tissue removal. A metallic marking clip can be placed during the procedure to facilitate future surgical excision if a diagnosis of cancer is determined. The procedure is generally well tolerated. Bleeding and hematoma are the most commonly encountered complications. Compared to conventional stereotactic biopsy, MRI-guided biopsy has a significantly higher cost. MRI-guided biopsy is a promising modality but requires further investigation as there are few long-term studies to determine histopathologic correlation and the false negative rate.¹⁹⁻²¹

Interpretation of Results

CNB is a highly accurate diagnostic tool: the false negative rate is only 1 to 2%,²² which is comparable to that of open wire-localized biopsy. When pathologic evaluation reveals fibroadenoma, microcalcifications within benign fibrocystic tissue, or other comparably benign pathologic conditions, there is no need for any special follow-up, and routine screening mammography may be resumed. However, when biopsy of the targeted mass lesion fails to yield a mass diagnosis or a biopsy specimen from a group of clustered calcifications is devoid of microcalcifications on pathologic review, the discordant result should be viewed with some suspicion and should be considered an indication for open biopsy. Subsequent excisional biopsy is also indicated when CNB reveals atypical hyperplasia, radial scar, lobular carcinoma in situ (LCIS), or papilloma. The rationale is that the excisional biopsy may result in a pathologic upgrade to cancer. For example, open biopsy after a CNB indicative of atypical ductal hyperplasia may reveal DCIS in approximately 40% of patients when CNB was performed with a 14-gauge automated gun. The use of larger (e.g., 11-gauge) core biopsy devices has reduced the frequency of this finding to approximately 20%,²³ but it has not eliminated the need for excision. False positive results are rare with CNB; therefore, a diagnosis of malignancy may be believed, and a one-stage definitive surgical procedure may then be planned without further biopsy.

Touch Preparation of Cores

For an immediate but preliminary diagnosis, cytologic touch preparation of fresh cores may be performed in the office.²⁴ The tissue is blotted to remove any gross blood, the core is gently smeared along a glass slide, and the slide is then immediately fixed in 70% ethanol. A layer of cells is left on the surface of the slide for cytologic evaluation, whereas the core is preserved for permanent evaluation. This procedure has a diagnostic accuracy of nearly 90%. Although the false negative rate is approximately 25%, an immediate diagnosis is obtained in 75% of patients.¹⁸ Like all preliminary diagnoses, touch preparation diagnoses should be treated with caution until the final results of histopathologic evaluation are available.

PERCUTANEOUS EXCISIONAL BIOPSY

In some instances, patient preference may dictate complete removal of a mass regardless of its benign appearance. As an alternative to open biopsy (see below), percutaneous excision of small masses may be performed.^{25–27} This procedure can be performed in an outpatient setting with the patient under local anesthesia. Some of the devices used for percutaneous excision are vacuum assisted and remove the mass as multiple cores, whereas others deliver large intact samples in a single pass [see *Figure 3*]. Although such approaches clearly show promise for future surgical treatment of breast cancer, these percutaneous devices are currently approved by the US Food and Drug Administration (FDA) only for excision of benign masses. Lesions found to be harboring cancer should undergo subsequent open surgical reexcision. Excision of lesions that are close to the skin or the chest wall or are larger than 2 to 3 cm in diameter may prove technically challenging with percutaneous techniques; open excisional biopsy [see *Open Biopsy, below*] may be preferable for such lesions.

OPEN BIOPSY

The vast majority of open breast biopsies are now performed with either local anesthesia alone or local anesthesia with intravenous sedation.

Technique

Various options for incisions are available [see *Figure 4*]. If the pathology is unclear, the incision is placed directly over the lesion to minimize tunneling through breast tissue. The incision should be long to ensure that the mass, together with a small rim of grossly normal tissue, can be excised as a single specimen and be oriented so that it can be included within any future lumpectomy or mastectomy incision should the lesion prove malignant. Resection of overlying skin is not necessary unless the lesion is extremely superficial. Historically, surgeons performing open biopsies have generally employed curvilinear incisions placed within the resting lines of skin tension [see *Figure 4, a and b*]. Currently, however, some surgeons are advocating the use of radial incisions, particularly for medial, lateral, and inferior lesions.¹⁵ If a previous CNB proved the lesion to be benign (e.g., fibroadenoma) but the patient still favors excision, it is acceptable to move the incision to a circumareolar position or another less visible site.

Figure 3 Percutaneous excisional biopsy. This procedure may be performed by means of several different methods. (a) One approach is to employ a vacuum-assisted device, which is placed with the trough under the lesion and the shaft parallel to the posterior aspect of the lesion. The needle is then lifted anteriorly as it is rotated first 45° clockwise, then back to the center position (0°), and finally 45° counterclockwise to remove the entire lesion in multiple cores. (b) Another option is to employ an electro-surgical device such as the Ovation (Rubicon Medical, Inc., Redwood City, California), which circumscribes the mass with a cutting wire loop while concurrently deploying a retractable plastic bag that encapsulates the lesion and retracts it through the skin en bloc. (c) A third option is to employ a device such as the Intact Breast Lesion Excision System (Intact Medical Corp., Natick, Massachusetts), which circumscribes the mass with a radiofrequency wand and delivers it en bloc.

For diagnostic biopsies, the surgeon should orient the specimen, and the pathologist should ink all margins. Meticulous hemostasis should be achieved before closure to prevent the formation of hematomas that could complicate subsequent definitive oncologic resection. A cosmetic subcuticular skin closure is preferred.

NEEDLE (WIRE)-LOCALIZATION BREAST BIOPSY

Lesions that are not amenable to stereotactic core biopsy may be excised by means of needle (wire)-localization breast biopsy (NLBB). Such lesions include those that are close to the chest wall or under the nipple, as well as those occurring in a thin breast, where firing the needle may cause it to pass through the opposite side of the breast. Radiographic evidence of a radial scar is also an indication for NLBB: a core pathologic diagnosis of such a scar would ultimately necessitate

Figure 4 Open biopsy. (a) For biopsy-proven benign masses, a circumareolar incision generally provides excellent cosmesis and a well-hidden scar. If the lesion is too far from the nipple, curvilinear incisions are traditionally employed instead. Alternatively, medial, lateral, and inferior incisions may be placed in a radial fashion. (b) For lesions of unknown pathology, incisions should be placed directly over the lesion and should be oriented so that they will be included within a subsequent mastectomy incision if margins prove positive and mastectomy is indicated. As with benign lesions, either curvilinear or radial incisions may be employed. Circumareolar incisions should be avoided in this setting because reexcision to provide clear margins, as is indicated in the case of malignancy, can necessitate excision of a portion of the nipple-areola complex and can commit the surgeon to a mastectomy. In cases where reexcision is indicated, avoidance of incisions in the so-called no man's land may improve cosmesis in that it allows future reconstructive efforts to include advancement of the nipple-areola complex if desired. Various oncoplastic incisions may be employed as alternatives for (c) medial, (d) central, or (e, f) superior lesions.

open excision. Finally, reexcision is required when stereotactic or ultrasound-guided CNB reveals lesions determined to be high risk on pathologic evaluation (e.g., atypical hyperplasia, LCIS, papilloma, carcinoma, or lesion whose pathologic status is discordant with radiographic findings). In these circumstances, wire localization may be performed on the residual lesion, a clip placed at the time of CNB, or another surrogate marker (see below). To bracket a more extensive area of calcifications, multiple wires may be placed, especially if previous CNB revealed atypia or malignancy in the area.

Technique

The lesion to be excised is localized by inserting a thin needle and a fine wire under mammographic, ultrasonographic, or MR guidance immediately before operation. To facilitate incision placement, images should be sent to the

operating room with the wire entry site indicated on them. The incision is placed as directly as possible over the mass to minimize tunneling through breast tissue. With superficial lesions, the wire entry site is usually close to the lesion and thus may be included in the incision. With some deeper lesions, the wire entry site is on the shortest path to the lesion and so may still be included in the incision. Once the incision is made, a block of tissue is excised around and along the wire in such a way as to include the lesion [see Figure 5, a and b]. This process is easier and involves less excision of tissue if the localizing wire has a thickened segment several centimeters in length that is placed adjacent to or within the lesion. The wire itself can then be followed into breast tissue until the thick segment is reached, at which point the excision can be extended away from the wire to include the lesion in a fairly small tissue fragment.

Figure 5 Needle-localization breast biopsy. (a) The mammographic abnormality is localized preoperatively. The relation between the wire, the skin entry site, and the lesion is noted by the surgeon. The skin incision is placed over the expected location of the mammographic abnormality. (b) The tissue around the wire is removed en bloc with the wire and sent for specimen mammography. Tunneling and piecemeal removal are to be avoided. (c) It is sometimes necessary to insert the localizing wire from a peripheral site to localize a deep or central lesion. The incision should be placed directly over the expected location of the lesion, not over the wire entry site. The dissection is extended into breast tissue to identify the wire a short distance from the lesion. The free end of the wire is pulled into the wound, and the biopsy is performed as previously described.⁹⁹

With many lesions, the wire entry site is in a fairly peripheral location relative to the position of the lesion, which means that including the wire entry site in the incision would result in excessive tunneling within breast tissue. In such cases, the incision is placed over the expected position of the lesion [see Figure 5c], the dissection is extended into breast tissue to identify the wire a few centimeters away from the lesion itself, and the free end of the wire is pulled up into the incision. A generous block of tissue is then excised around the wire. Intraoperative ultrasonography may be useful for identifying the tip of the needle and facilitating excision, particularly in the case of a deep lesion or biopsy site in a large breast.

Radiography should be performed intraoperatively on all wire-localized biopsy specimens to confirm excision of the lesion. If the lesion was missed, another tissue sample may be

Figure 6 Hematoma ultrasound-guided excision. (a) The hematoma is localized in two planes with intraoperative ultrasonography, and 1 cm margins are marked off around it. Dissection then proceeds down toward the chest wall in a block fashion. Excision of the hematoma is confirmed by ultrasonography of the specimen ex vivo. (b) as well as by direct visualization of the hematoma in the gross specimen.^{31,32}

excised if the surgeon has some idea of the likely location of the missed lesion. If, however, the surgeon suspects that the wire was dislodged before or during the procedure, then the incision should be closed, and repeat localization and biopsy should be performed later. In addition to wire dislocation or transection, wire localization is occasionally associated with vasovagal reactions. Alternatives to wire localization include hematoma ultrasound-guided (HUG) excision (see below), carbon marking,²⁸ use of methylene blue dye,²⁹ and placement of radioactive seeds.³⁰

Hematoma ultrasound-guided excision In patients who have undergone CNB, particularly those who have undergone VACB, the hematoma at the biopsy site can often serve as a physiologic marker that accurately guides intraoperative localization [see Figure 6].^{31,32} This procedure, referred to as HUG excision, renders wire placement unnecessary and can facilitate operative scheduling. The hematoma is localized in two planes using ultrasound guidance and 1 cm margins are marked off around the lesion; dissection is then continued down toward the chest wall in a block fashion. Excision of the hematoma can be confirmed by ultrasonography of the specimen ex vivo, as well as direct visualization of the hematoma in the gross specimen. Another variation of the procedure includes localization of the tumor with MRI and infusion of the patient's own blood into the lesion for future localization and surgical excision.³¹

RADIOISOTOPE-GUIDED OCCULT LESION LOCALIZATION

As widespread mammographic screening programs have been employed, there has been an increase in the detection of nonpalpable breast lesions requiring improved localization techniques for biopsy and/or excision. Radioisotope-guided occult lesion localization (ROLL) is one such modality using an intratumorally injected radiotracer to identify the lesion intraoperatively by use of a gamma probe.³³ Contraindications

to the ROLL procedure include patients with a history of albumin allergy attributed to the injection of a colloid into the breast lesion.³⁴ The ROLL procedure has shown a decrease in the volume of breast tissue excised while preserving surgical margins. Patients have reported less pain and an improved cosmetic result with this procedure.^{34–36} Clinical trials have shown adequate excision rates when compared with the needle-localization technique. Combination with the sentinel lymph node (SLN) mapping procedure has been successfully described in the literature.^{37–39} Further investigation with randomized clinical trials is currently underway.

Technique

Lesions are identified by image guidance using either ultrasonography or stereotactic mammography, and intratumoral injection of a radionuclide-labeled colloid is performed prior to surgery. The procedure can be performed using local anesthesia with or without sedation. Intraoperatively, a handheld gamma-detecting probe is used to identify the area with the maximum radioactivity, and a small incision is made in the skin overlying this site. Determination of excision volume is made by review of preoperative lymphoscintigraphic imaging and decreased detection of radioactivity in the resection bed. Surgical specimens should undergo radiographic evaluation to confirm removal of the lesion.

Terminal Duct Excision

Terminal duct excision is the procedure of choice in the surgical treatment of pathologic nipple discharge.⁴⁰ The goal is to excise the discharging duct with as little additional tissue as possible to maintain cosmesis. To this end, the surgeon should carefully note the precise position of the offending duct at the time of the initial examination. To ensure accurate ductal identification, intraductal injection of methylene blue has been used to aid in visualization of the involved ductal system prior to major duct excision. Other methods used in conjunction with terminal duct excision to limit the volume of tissue removed include ductography and ductoscopy.⁴¹

OPERATIVE TECHNIQUE

The patient is instructed to refrain from manually expressing her discharge for several days before operation. After local anesthesia (with or without sedation) is administered, the surgeon attempts to express the discharge. If this attempt is successful, the edge of the nipple is grasped with a forceps, and a fine lacrimal duct probe (000 to 0000) is gently inserted into the discharging duct. A radial incision is made within the areola at the same clock position as is occupied by the draining duct [see Figure 7]; this incision is preferred to a circumareolar incision because it is believed to preserve more nipple sensation and function.⁴² The nipple skin flap is raised, and the duct containing the wire is excised with a margin of surrounding tissue from just below the nipple dermis to a depth of 4 to 5 cm within the breast tissue. The electrocautery should be employed with particular caution in the superficial portions of the dissection to prevent devascularization of the nipple-areola complex. If it is not possible to pass the lacrimal duct probe into the discharging duct or it is unclear which duct has resulted in the pathologic discharge, the entire

Figure 7 Terminal duct excision. (a) A radial incision is made within the areola. (b) The involved duct is identified by means of blunt dissection and removed along with a core of breast tissue. (c) If no single duct is identified, the entire subareolar ductal complex is excised from immediately beneath the nipple dermis to a depth of 4 to 5 cm within breast tissue.^{40,42}

subareolar duct complex must be excised from immediately beneath the nipple dermis to a depth of 4 to 5 cm within the breast tissue. The breast tissue should be reapproximated beneath the nipple to prevent retraction of the nipple or indentation of the areola.

Minimally Invasive Techniques

The next step in the evolving application of minimally invasive techniques to breast cancer is to determine whether ablative local therapies can safely substitute for standard surgical extirpation. Cryotherapy, interstitial laser therapy, radiofrequency ablation (RFA), microwave ablation, and high-intensity focused ultrasound ablation have all been studied as means of eradicating small breast cancers.⁴³ In most of these techniques, a probe is placed percutaneously into the breast lesion under imaging guidance, and tumor cell destruction is achieved by means of either heat or cold.

To date, experience with ablative breast therapies has been limited, and long-term follow-up has not been carried out. There is some evidence that patients who have small, well-defined, unifocal cancers without an extensive intraductal component may have greater success with these techniques.⁴³ Lesions in close proximity to the pectoralis major muscle or the skin should be isolated by injecting normal saline to prevent thermal injury. Most of the time, these minimally

invasive techniques are well tolerated and can be performed in an outpatient setting. Additionally, superior cosmesis is achieved by leaving the ablated tissue in situ without loss of tissue volume, thus preventing breast deformity and scarring. However, most of the initial studies of ablative breast therapies involved subsequent surgical excision to obtain histologic evidence of cell death. Unfortunately, when ablative therapies are used alone, the benefits of pathologic assessment of the specimen, including evaluation of margin status, are lost. Limiting factors include the ability of current imaging modalities to detect residual disease, thereby identifying patients who may need subsequent surgical intervention. Clearly, minimally invasive ablative approaches to breast cancer are technically feasible and safe, and they do appear to offer some potential advantages; however, it remains to be determined to what extent they are oncologically appropriate.

CRYOABLATION

Cryotherapy has been successfully used in the treatment of nonresectable liver tumors. It destroys targeted tissue by alternately freezing (-40°C) and thawing the lesion. Intracellular ice formation and osmotic and ischemic injury are believed to contribute to the mechanism of tissue destruction. Because of the natural analgesic effect of cold, cryoablation is generally a well-tolerated procedure that can be performed in an outpatient setting using local anesthesia with minimal need for pain-controlling medications.

Patients with a biopsy-proven fibroadenoma who want their mass removed but desire an alternative to open or percutaneous surgical excision may be candidates for cryoablation. Clinically, resorption of the fibroadenoma increases over time, with 12-month follow-up studies reporting a significant reduction in lesion volume. Despite the occasional residual disease noted when cryoablation is used to treat larger masses, both hospital- and community-based studies have reported that patient satisfaction rates are higher than 90% with this procedure.⁴⁴

The role of cryotherapy in the treatment of primary malignant disease has recently been explored. Immunologic activation from the cryoablative technique may provide an effective tumor-specific response.⁴⁵ Early studies reveal the degree of tumor destruction achieved by cryotherapy to be inconsistent.^{46–48} Larger clinical trials are currently in the planning stages, and the efficacy of this treatment for selected patient populations remains investigational.

Use of the cryoprobe has also been explored as an alternative to needle localization for excision of nonpalpable lesions prior to BCT. Theoretically, the ability to palpate previously nonpalpable lesions may reduce reexcision rates for positive margins. Pilot studies have shown decreases in resected tissue volume, improved cosmesis, and improved patient satisfaction with a consistently negative margin status.⁴⁹ Clearly, the use of cryoablation in this role also requires further examination.

Technique

A 12-gauge cryoprobe is inserted into the center of the lesion under ultrasonographic guidance. To freeze the lesion, inert argon gas is delivered through the tip of the probe in such a way as to create a local temperature of -40°C or

Figure 8 Cryoablation. The needle is placed through the center of the lesion, and argon gas is delivered to create a local temperature of -40°C . The resulting iceball is well visualized by ultrasonography.

lower. An iceball is thereby formed that is well visualized by ultrasonography [see Figure 8]. In a tightly coupled system, helium is then delivered to thaw the lesion. For adequate necrosis to occur, two freeze-thaw cycles must be performed; the exact specifications of these cycles depend on the size of the lesion.

INTERSTITIAL LASER THERAPY

Interstitial laser therapy causes hyperthermic (80°C to 100°C) cell death and coagulative tissue necrosis by delivering energy through a fiberoptic probe. Precise targeting with the use of an MRI-guided laser or stereotactic mammography is required. Benefits of this treatment include the use of local anesthesia only. One reported complication with significant morbidity included gaseous rupture of the tumor.⁴⁶ Small studies employing surgical excision following laser treatment have shown complete ablation to be inconsistent. Smaller tumors were more likely to be completely ablated.^{50,51} Complete tumor destruction has been difficult to ensure with this technique. Further investigation and long-term follow-up are required.

Technique

A 16-gauge needle with a thermal sensor is inserted into the center of the tumor using image guidance. The stylet is then replaced with a laser fiber, and the tissue is heated to 80°C to 100°C . For larger lesions, multiple laser fibers may be placed. A thermal sensor needle is placed 1 cm away from the laser needle to monitor peripheral temperatures and ensure an ablative zone of 2.5 to 3.0 cm. Tumor destruction is confirmed by ultrasonography or MRI.⁵⁰

RADIOFREQUENCY ABLATION

Like cryotherapy, RFA has also been extensively used to treat liver tumors. RFA is a minimally invasive thermal ablation technique in which frictional heat is generated by intracellular ions moving in response to alternating current. It is

currently the most promising ablative method for small breast cancers; however an accurate treatment algorithm remains to be developed.⁵⁰ Complications include superficial skin burning and temporary elevation of body temperature. Early studies with RFA followed by immediate or delayed surgical resection have shown incomplete ablation of tumors.⁴⁶ Incomplete ablations were attributed to large tumor size (> 2 cm) and the presence of multifocal disease.⁴³

Technique

A large-gauge probe is placed into the center of the tumor using image guidance. A star-shaped set of electrodes is deployed from the tip of the probe to deliver heat at a temperature of 95°C, which is maintained for 15 minutes followed by a period of cooling for 1 minute. Postprocedural MRI may help confirm complete tumor destruction after RFA and other ablative techniques.

MICROWAVE ABLATION

Microwave ablation is an investigational technique similar to RFA causing tumor necrosis by generation of frictional heat using two microwave phased array applicators. Because of the higher water content of cancer tissue (compared to adipose and glandular tissue), agitation of intracellular water molecules causes temperature elevation of the breast lesion, leading to tissue necrosis. Image guidance is usually performed to localize the lesion. Complications have included skin flap necrosis and mild skin burns overlying the treatment area. Pilot studies have shown a reduction in the size of the tumor; however, further prospective trials are needed to investigate the use of microwave ablation as a treatment modality for invasive cancer.^{52–55} Current investigations into the added benefit of microwave ablation in conjunction with neoadjuvant chemotherapy are promising.⁵⁴

FOCUSED ULTRASOUND ABLATION

Focus ultrasound ablation (FUS) is a modality used to incur cellular death by thermal injury from an ultrasonic energy source. One of the benefits of FUS is that no implantable device is required, allowing the procedure to be performed through the intact skin. Additionally, larger tumors and lesions with an irregular shape can be ablated using this technique. Image guidance is required to make sure the lesion is adequately ablated including a 2 cm margin, in keeping with the oncologic principles of breast conservation surgery. Short-term follow-up studies ablating smaller tumors have shown contradictory results with FUS regarding complete tumor necrosis. A palpable lump following the procedure is noted by most patients from local tissue edema; however, this is transient and usually resolves within 1 to 2 weeks. Contraindications to FUS include multifocal, deep lesions and tumors in close proximity to the skin and nipple.^{54–56}

Surgical Options for Breast Cancer

There are several surgical options for primary treatment of breast cancer. It should be emphasized that for most patients, partial mastectomy (lumpectomy) to microscopically clear margins coupled with axillary staging and radiation therapy yields long-term survival equivalent to that associated with mastectomy and axillary staging. Currently, indications for

mastectomy include patient preference, the inability to achieve clean margins without unacceptable deformation of the breast, the presence of disease in multiple quadrants (multicentric disease), previous chest wall irradiation, pregnancy, the presence of severe collagen vascular disease (e.g., scleroderma), and the lack of access to a radiation therapy facility.

Partial Mastectomy

Partial mastectomy—also referred to as wide local excision or lumpectomy—involves excision of all cancerous tissue to microscopically clear margins. Although 1 cm margins are the goal, many surgeons consider 2 mm margins to be adequate for reducing the risk of local recurrence.⁵⁷ Hence, reexcision is indicated whenever margins are either positive or too close (< 2 mm). Partial mastectomy is commonly performed with the patient under local anesthesia, with or without sedation. The addition of an axillary staging procedure (a common event) usually necessitates general anesthesia, but in select circumstances, local or epidural anesthesia may suffice.

OPERATIVE TECHNIQUE

An incision is placed directly over the lesion to minimize tunneling through breast tissue; it should be oriented so as to be included within a subsequent mastectomy incision if margins prove positive. As with open biopsy (see above), curvilinear incisions have been the standard, but radial incisions are now being advocated by some surgeons, particularly for upper outer, medial, lateral, and inferior lesions. A radial incision facilitates excision of tumors that extend in a ductal distribution, preserves the contour of the breast, and permits easier reexcision if margins prove positive [see *Figure 4b*]. With current oncoplastic techniques,^{58,59} lesions in the central, medial, or superior portions of the breast can be resected with minimal cosmetic deformity [see *Figure 4, c, d, e, and f*]. Resection of a portion of the overlying skin is not necessary unless the lesion is extremely superficial.

To obtain clear margins, a 1 to 1.5 cm margin of normal-appearing tissue should be removed beyond the edge of the palpable tumor or, if excisional biopsy has already been performed, around the biopsy cavity. In the case of nonpalpable lesions diagnosed by means of CNB, wire localization is performed, and 2 to 3 cm of tissue should be excised around the wire to obtain an adequate margin. Intraoperative ultrasonography may reduce the rate of positive margins by allowing visualization of the tumor edge or the previous biopsy site.⁶⁰

The specimen should be oriented by the surgeon and the margins inked by the pathologist; this orientation is useful if reexcision is required to achieve clean margins. Reexcision of any close (< 2 mm) margins may be performed during the same surgical procedure if the specimen margins are assessed immediately by the pathologist. If the specimen was not oriented, the entire biopsy cavity should be reexcised. Surgical clips may be left in the lumpectomy site to help the radiation oncologist plan the radiation boost to the tumor bed or to direct partial-breast irradiation. In the closure of the incision, hemostasis should be meticulous: a hematoma may delay adjuvant therapy. Deep breast tissue should be approximated only if such closure does not result in significant deformity of breast contours. A cosmetic subcuticular closure is preferred.

Wearing a support bra during the day and night can reduce shearing of fragile vessels.¹⁵

ACCELERATED PARTIAL-BREAST IRRADIATION WITH BALLOON CATHETER

Historically, whole-breast irradiation has been the standard treatment to reduce the risk of local recurrence after BCT. Long-term follow-up of patients who have received BCT demonstrates, however, that only 1 to 3% of recurrences within the breast arise at a significant distance from the primary cancer site (i.e., in other breast quadrants); the remainder develop near the original biopsy site.^{57,61} These data provide the rationale for the approach known as accelerated partial-breast irradiation (APBI), in which a shortened course of high-dose radiation is delivered to the tissue surrounding the lumpectomy cavity (the region theoretically at greatest risk). Decreasing the volume of tissue receiving radiation therapy allows for patients to undergo a shorter course of therapy (approximately 1 week).⁶² Several different APBI techniques have been developed, including placement of interstitial catheters, use of a localized external beam, single-dose intraoperative treatment, implantation of radioactive beads or seeds, and insertion of a balloon catheter into the lumpectomy site. Although long-term follow-up has not been carried out, the short-term results reported for some APBI techniques indicate that in most centers, recurrence rates have been low, with good cosmesis and only mild chronic toxicity.⁶³

The technique of APBI can be illustrated by considering the MammoSite Radiation Therapy System (Cytac Corp., Palo Alto, California), in which a balloon catheter is inserted into the surgical cavity after lumpectomy to provide partial-breast irradiation (see below). Although the catheter may also be inserted at the time of the original operation, it is preferable to wait for final pathologic evaluation to confirm clear margins; if the catheter is inserted and margins are found to be positive, it will have to be replaced (a costly process). The optimal time for insertion of the APBI balloon is within 2 to 3 weeks from the final procedure. Postoperative insertion may be done either percutaneously under ultrasonographic guidance or by means of an open technique. Once the catheter is in place, a radiation source (iridium 192) is delivered into the balloon via a high-dose rate remote afterloader.

Technique

For safe and effective delivery of radiotherapy through the MammoSite balloon catheter, the lumpectomy cavity must be able to conform its shape to that of an ovoid or spherical catheter without significant air pockets, able to accommodate a volume of at least 30 mL (the volume of the smallest available balloon), and able to maintain a minimum distance of 7 mm from the skin with the catheter in place. In addition, if a percutaneous technique is being considered, the surgeon should be comfortable with ultrasonography (which will be employed for initial visualization of the lumpectomy cavity). If the above criteria seem reasonably attainable, one may proceed with a percutaneous approach [see Figure 9].

Percutaneous approach A site peripheral to the scar is chosen as the entry site for the balloon catheter, and a local anesthetic is injected along the proposed catheter tract.

Figure 9 Accelerated partial-breast irradiation with balloon catheter. (a) The lumpectomy cavity is evaluated by means of ultrasonography. (b) The trocar is inserted through a separate entry site under ultrasonographic guidance. (c) The uninflated balloon catheter is advanced through the trocar path. (d) Under ultrasonographic visualization, the balloon is inflated with saline or contrast material. An anterior distance of at least 7 mm between the catheter and the chest wall or skin is confirmed.

A trocar (supplied with the insertion kit) is inserted into the cavity via the peripheral entry site and then removed. Removal of the trocar allows for the evacuation of the postlumpectomy seroma and prevents underdosage of tissue around the cavity. The shape of the cavity and skin-to-cavity distance are visualized by means of ultrasonography, and a catheter of appropriate shape (ovoid or spherical) and volume (30 to 65 mL) is advanced through the newly formed tract. Saline is then infiltrated to inflate the catheter balloon to the maximum volume that the cavity can accommodate. A small amount of radiographic contrast may also be infused to aid in visualization. The cavity is then reimaged to confirm that the catheter is an adequate distance (7 mm) from the skin. If the distance is inadequate, the balloon volume is reduced. If it is not possible to keep the catheter at least 7 mm from the skin while maintaining a balloon volume of at least 30 mL, conversion to an open approach is indicated.

Open approach The cavity is reopened through the original skin incision. Occasionally, a thick rind may form around the residual seroma; this rind may be excised to reduce tension and increase the volume of the cavity. If necessary, the anterior skin may be excised in the form of an ellipse to provide improved anterior coverage of the catheter, and the subcutaneous tissue may be pulled together over the catheter and the cavity to help ensure adequate coverage and sufficient distance from the skin. A peripheral site is chosen for insertion of the catheter. After the skin is closed, ultrasonography is employed to confirm that the distance from the

skin is adequate. A topical antibiotic is applied at the insertion site; no anchoring stitch is necessary. Correct positioning of the catheter is confirmed by a postplacement treatment-planning computed tomographic (CT) scan that is evaluated by the radiation oncologist.

Mastectomy

The goal of a mastectomy is to remove all breast tissue—including the nipple, the areola, and the pectoral fascia—while leaving viable skin flaps and a smooth chest wall for application of prosthesis. This should be the objective whether the mastectomy is performed for cancer treatment or for prophylaxis. Skin-sparing mastectomy (SSM) performed in conjunction with immediate reconstruction is discussed elsewhere [see Breast Reconstruction, *below*]. Proper skin incisions and good exposure are the key components of a well-performed mastectomy. Mastectomy usually calls for general anesthesia, but it may be performed with thoracic epidural anesthesia or local anesthesia in select circumstances.

OPERATIVE TECHNIQUE

The traditional mastectomy incision is an elliptical one that is placed either transversely across the chest wall or at an upward angle toward the axilla. It should be fashioned in such a way as to include the nipple-areola complex and any incision from a previous biopsy [see Figure 10a]. Ideally, the upper and lower skin flaps should be of similar length so that there is no redundant skin on either flap. The outline of the incision may be established by using the following five steps:

1. The lateral and medial end points are marked.
2. The breast is pulled firmly downward.
3. To define the path of the upper incision, a straight line is drawn from one end point to the other across the upper surface of the breast.
4. The breast is pulled firmly upward.
5. To define the path of the lower incision, a straight line is drawn from one end point to the other across the lower surface of the breast.

The outlined incision is then checked to confirm that it can be closed without either undue tension or redundant skin. Dog-ears or lateral skin folds can be prevented by extending the incision medially or laterally to remove all the skin that contributes to the forward projection of the breast. The closure should be fairly snug intraoperatively while the arm is extended; significant slack will be created when the arm is returned to the patient's side. The medial and lateral end points of the incision may be adjusted upward or downward to include any previous biopsy incisions.

As noted [see Partial Mastectomy, *above*], there is increasing acceptance of the use of radial and oncoplastic incisions for BCT. In a small percentage of women, persistently positive margins may dictate conversion from BCT to mastectomy. In large-breasted women with excess breast skin, traditional elliptical incisions can easily incorporate any previous radial or superior-pole oncoplastic incisions that may have been performed [see Figure 10b]. In smaller-breasted women, however, sigmoid, modified Wise, or other oncoplastic mastectomy incisions may be needed to incorporate previous lumpectomy incisions [see Figure 10c].

Figure 10 Mastectomy incisions. (a) Elliptical incisions incorporate traditional lumpectomy incisions. (b) In large-breasted women with excess breast skin, traditional ellipses can easily incorporate previous radial and superior-pole oncoplastic incisions. (c) In smaller-breasted women, sigmoid, modified Wise, or other oncoplastic mastectomy incisions may be needed to incorporate previous radial lumpectomy incisions.

Once the incision is made, the next step is to create even and viable flaps. In most patients, there is a fairly well-defined avascular plane between subcutaneous fat and breast tissue. This plane is identified by pulling the edges of the incision upward with skin hooks and beginning a flap that is 8 to 10 mm thick. After an initial release of the skin edge, the desired plane is developed by applying firm tension downward on the breast tissue and away from the skin at a 45° angle. The fine fibrous attachments between breast tissue and subcutaneous fat (Cooper ligaments) are then divided

with the electrocautery or a blade, and crossing vessels are coagulated or ligated as they appear. To protect both arterial supply to and venous drainage from the skin flap, one must refrain from excessive ligation or cauterization of vessels on the flap. For most women, flap viability is not an issue. For diabetics, smokers, and other patients with diffuse small vessel disease, however, it is a serious consideration. In such patients, flaps should be no longer than necessary with no excess tension, and extra care should be taken to preserve flap vessels. Patients should be warned that even with these measures, there may be some skin necrosis along the incision. Such necrosis is best treated with gradual débridement of the eschar.

Flaps are raised superiorly to the clavicle, medially to the sternum, inferiorly to the inframammary fold, and laterally to the border of the latissimus dorsi. The pectoral fascia is incised both superiorly and medially. Inferiorly, the fascia of the abdominal muscles is not divided. The pectoralis major, the abdominal muscles, and the anterior serratus muscle form the deep border of the dissection. The pectoral fascia is removed with the breast specimen and may be separated from the muscle with either the electrocautery or a blade.

In a simple mastectomy, the dissection proceeds around the lateral edge of the pectoralis major but stops before entering the axillary fat pad (unless the procedure is being done in conjunction with SLNB). A single closed suction drain is placed through a separate lateral stab wound in such a way that it extends under the lower flap and a short distance upward along the sternal border of the dissection.

A modified radical mastectomy essentially consists of an axillary node dissection added to a simple mastectomy. At the lateral edge of the dissection, the border of the latissimus dorsi is exposed, as is the lateral border of the pectoral muscle. Retraction of these two muscles provides excellent exposure for the axillary dissection [see Axillary Dissection, *below*]. Some surgeons prefer to remove the breast from the chest wall first, whereas others leave the breast attached to provide tension for the axillary dissection. On completion of the procedure, two closed suction drains are placed, one in the axilla and another under the lower flap and extending to the midline.

After either a simple or a modified radical mastectomy, the skin is closed and a dressing applied according to the surgeon's preference. Early arm mobilization is encouraged.

SKIN-SPARING MASTECTOMY

SSM, which consists of resection of the nipple-areola complex, any existing biopsy scar, and the breast parenchyma, followed immediately by breast reconstruction, has become an increasingly popular approach for women requiring mastectomy.⁶⁴ With this approach, the inframammary fold and contour of the breast are preserved, and a generous skin envelope remains in situ for reconstruction; cosmetic results are thereby optimized. In addition, SSM is oncologically safe and is not associated with an increased incidence of local recurrence.⁶⁵ The recurrences that do occur typically develop below the skin flaps and thus are easily detectable; deep recurrences beneath the reconstruction are comparatively uncommon.

The incision for SSM with immediate reconstruction should be planned in collaboration with the plastic surgeon [see Figure 11], and the inframammary fold should be marked

preoperatively with the patient in a sitting position. Several options are available for SSM. For CNB-diagnosed tumors that are not superficial, a circumareolar incision may be employed, with a lateral extension for exposure if necessary. Different incisions may be used if it proves necessary to incorporate previous incisions or to remove skin anterior to superficial tumors. A separate axillary incision may be useful when axillary dissection or SLNB is being performed. CNB sites generally are not included in the excised skin segment; the surgeon may opt to excise them through a separate skin ellipse. Intraoperatively, flaps are created in a circular fashion to optimize exposure. Although optimal cosmesis is part of the rationale for SSM, cosmetic considerations should never be allowed to compromise the extent of the dissection in any way.

NIPPLE-SPARING MASTECTOMY

Following mastectomy or SSM, many patients report dissatisfaction with the reconstruction of their nipple areolar complex using skin grafting or tattooing. Nipple-sparing mastectomy (NSM) eliminates the need for reconstruction by preservation of the dermis and epidermis of the nipple-areola complex during the initial procedure. Several initial studies have shown NSM to be an oncologically safe procedure in those patients appropriately selected.⁶⁶⁻⁷¹ Contraindications to NSM include larger tumors (> 2 cm), centrally located lesions with a small tumor-to-nipple distance, and lymphovascular invasion.⁷²

Several types of incisions have been described, including periareolar with lateral extension, transareolar with lateral extension, and inframammary fold incisions. These typically allow for good exposure and dissection of the retroareolar structures.⁷³ Elevation of the areola off of the breast parenchyma should be performed with sharp dissection to prevent thermal injury to the nipple from electrocautery. The lactiferous ducts are transected at the base of the nipple papilla. Skin flaps are raised in a manner similar to that of SSM or conventional mastectomy. On removal of the subcutaneous breast, the remaining nipple tissue is removed with sharp dissection. A small (2 to 3 mm) rim of peripheral subcutaneous tissue should be preserved behind the nipple to prevent partial or complete nipple necrosis. Pathologic evaluation of the excised lactiferous ducts for tumor involvement is imperative

Figure 11 Shown is (a) the recommended placement of the traditional circumareolar incision for skin-sparing mastectomy. (b) Separate incisions may be used to excise previous lumpectomy incisions or to gain access to the axilla. (c) A lateral extension can provide further exposure for flap development or axillary staging.

and mandates complete removal of the nipple if in situ or invasive disease is present.

One of the most concerning complications to NSM includes nipple or areolar necrosis, which not only negatively impacts cosmesis but can cause loss of the reconstructed implant. Additional complications include lack of sensation to the nipple, change in nipple pigmentation, and improper nipple positioning following reconstruction.⁷⁴ Currently, long-term follow-up to investigate local recurrence rates for NSM is lacking. However, NSM appears to be a good option for those patients undergoing prophylactic mastectomy or those with small, peripheral tumors or in situ disease.

Lymphatic Mapping and SLNB

The pathologic status of the axillary nodes is the single most important prognostic factor for outcome after treatment of breast cancer. The growing recognition of the morbidity of traditional axillary dissection (lymphedema and sensory deficits), together with the increased capability of mammography to detect smaller, potentially node-negative invasive breast cancers, has given rise to the development of SLNB as an axillary staging procedure. SLNB is a minimally invasive means of identifying the first node or nodes draining the breast and hence the first node or nodes to which tumor may spread. In experienced hands, a negative SLNB reliably predicts a tumor-free axilla (false negative rate, 5 to 9%); therefore, when such a result is obtained, no further nodes need to be removed and the patient can be spared the morbidity of a traditional axillary node dissection.⁷⁵⁻⁷⁷ Surgeons competent in SLNB should be able to identify the SLN with at least 90% accuracy and a false negative rate lower than 5%.⁷⁸ It is recommended that surgeons first learning the technique use axillary dissection as a backup for the first 20 procedures to gain experience in identifying the SLN. Currently, axillary dissection is recommended for patients who have a positive SLN; however, prospective, randomized trials are required to determine the extent to which this step is necessary in SLN-positive patients.

The most common method of identifying the SLN involves injection of both a vital blue dye and a radionuclide.⁷⁹⁻⁸² The radionuclide is first injected into the subareolar lymphatic plexus, either preoperatively or, in some centers, intraoperatively.⁸⁰ Because the breast and its overlying skin drain to the same few SLNs,⁸² peritumoral, intradermal, and subareolar injections are all acceptable approaches; subareolar injection has the advantage of being expeditious and accurate in cases of multicentric (as well as unicentric) disease.⁷⁹ The vital blue dye is then injected, commonly in the subareolar plexus, and the breast is massaged for 5 minutes to stimulate lymphatic flow. Lymph nodes that are “hot” (i.e., radioactive), blue, or both, as well as palpable nodes, are removed for evaluation by frozen-section analysis or touch-print cytology.

SLNB has also been employed in DCIS patients, but, in general, its use should be limited to patients with extensive DCIS who are undergoing mastectomy (in the event of occult invasive disease). Some investigators recommend SLNB for patients with extensive DCIS who are undergoing BCT (in whom CNB may have missed an area of invasion),⁸³ whereas others caution against this practice.^{84,85} Results from

the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-27 trial suggest that in patients undergoing neoadjuvant therapy, SLNB may be performed either before or after therapy, with no significant differences in identification and false negative rates⁸⁶; however, this suggestion is not universally accepted.⁸⁷ Contraindications to SLNB include the presence of clinically positive axillary nodes, previous axillary surgery, and pregnancy or lactation. Large or locally advanced breast cancers commonly give rise to a positive SLN but are not a contraindication to the procedure in that some patients may still be spared the morbidity of a full axillary dissection.

Axillary Dissection

Before the advent of SLNB, axillary dissection was routinely performed in breast cancer patients. It provided prognostic information that guided subsequent adjuvant therapy, afforded excellent local control, and may have contributed a small overall survival benefit.

Axillary dissection includes resection of level I and level II lymph nodes [see Figure 12a].⁸⁸ The superior border of the dissection is formed by the axillary vein; the lateral border of the dissection is formed by the latissimus dorsi; the medial border is formed by the pectoral muscles and the anterior serratus muscle; and the inferior border is formed by the tail of the breast. Level II nodes are easily removed by retracting the pectoralis major and the pectoralis minor medially; it is not necessary to divide or remove the pectoralis minor. Level III nodes are not removed unless palpable disease is present.

Axillary dissection, either alone or in conjunction with lumpectomy or mastectomy, usually calls for general anesthesia, but it may be performed with thoracic epidural anesthesia. To facilitate identification and preservation of motor nerves within the axilla, the anesthesiologist should refrain from using neuromuscular blocking agents. In the absence of neuromuscular blockade, any clamping of a motor nerve or too-close approach to a motor nerve with the electrocautery will be signaled by a visible muscle twitch.

STRUCTURES TO BE PRESERVED

A number of vascular structures and nerves passing through the axilla must be preserved during axillary dissection [see Figure 12b]. These structures include the axillary vein and artery; the brachial plexus; the long thoracic nerve, which innervates the anterior serratus muscle; the thoracodorsal nerve, artery, and vein, which supply the latissimus dorsi; and the medial pectoral nerve, which innervates the lateral portion of the pectoralis major.

The axillary artery and the brachial plexus should not be exposed during axillary dissection. If they are, the dissection has been carried too far superiorly, and proper orientation at a more inferior position should be established. In some patients, there may be sensory branches of the brachial plexus superficial (and, rarely, inferior) to the axillary vein laterally near the latissimus dorsi; injury to these nerves results in numbness extending to the wrist. To prevent this complication, the axillary vein should initially be identified medially, under the pectoralis major. Medial to the thoracodorsal nerve and adherent to the chest wall is the long thoracic nerve of

Bell. The medial pectoral nerve runs from superior to the axillary vein to the undersurface of the pectoralis major, passing through the axillary fat pad and across the level II nodes; it has an accompanying vein whose blue color may be used to identify the nerve. If a submuscular implant reconstruction [see Breast Reconstruction, *below*] is planned, preservation of the medial pectoral nerve is especially important to prevent atrophy of the muscle.

The intercostobrachial nerve provides sensation to the posterior portion of the upper arm. Sacrificing this nerve generally leads to numbness over the triceps region. In many women, the intercostobrachial nerve measures 2 mm in diameter and takes a fairly cephalad course near the axillary vein; when this is the case, preservation of the nerve will not interfere with node dissection. Sometimes, however, the nerve is tiny, has multiple branches, and is intermingled with nodal tissue that should be removed; when this is the case, one should not expend a great deal of time on attempting to preserve the nerve. If the intercostobrachial nerve is sacrificed, it should be transected with a knife or scissors rather than with the electrocautery, and the ends should be buried to reduce the likelihood of postoperative causalgia.

OPERATIVE TECHNIQUE

The incision for axillary dissection should be a transverse or curvilinear one made in the lower third of the hair-bearing skin of the axilla. For cosmetic reasons, it should not extend anteriorly onto the pectoralis major; however, it may be

extended posteriorly onto the latissimus dorsi as necessary for exposure. Skin flaps are raised to the level of the axillary vein and to a point below the lowest extension of hair-bearing skin, either as an initial maneuver or after the initial identification of key structures.

The key to axillary dissection is obtaining and maintaining proper orientation with respect to the axillary vein, the thoracodorsal bundle, and the long thoracic nerve. After the incision has been made, the dissection is extended down into the true axillary fat pad through the overlying fascial layer. The fat of the axillary fat pad may be distinguished from subcutaneous fat on the basis of its smoother, lipomalike texture. There may be aberrant muscle slips from the latissimus dorsi or the pectoralis major; in addition, there may be an extremely dense fascial encasement around the axillary fat pad. It is important to divide these layers early in the dissection. The borders of the pectoralis major and the latissimus dorsi are then exposed, which clears the medial and lateral borders of the dissection.

The axillary vein and the thoracodorsal bundle are identified next. As discussed (see above), the initial identification of the axillary vein should be made medially, under the pectoralis major, to prevent injury to low-lying branches of the brachial plexus. Sometimes, the axillary vein takes the form of several small branches rather than a single large vessel. If this is the case, all of the small branches should be preserved.

The thoracodorsal bundle may be identified either distally at its junction with the latissimus dorsi or at its junction with the axillary vein. The junction with the latissimus dorsi is

Figure 12 Axillary dissection.⁸⁸ (a) Shown are axillary lymph node levels in relation to the axillary vein and the muscles of the axilla (I = low axilla, II = midaxilla, III = apex of axilla). (b) Shown is a view of the structures of the axilla after completion of axillary dissection.

within the axillary fat pad at a point two thirds of the way down the hair-bearing skin of the axilla, or approximately 4 cm below the inferior border of the axillary vein. Occasionally, the thoracodorsal bundle is bifurcated, with separate superior and inferior branches entering the latissimus dorsi; this is particularly likely if the entry point appears very high. If the bundle is bifurcated, both branches should be preserved. The thoracodorsal bundle may be identified at its junction with the latissimus dorsi by spreading within axillary fat parallel to the border of the muscle and looking for the blue of the thoracodorsal vein. Identification is also facilitated by lateral retraction of the latissimus dorsi. The long thoracic nerve lies just medial to the thoracodorsal bundle on the chest wall at this point and at approximately the same anterior-posterior position. It may be identified by spreading tissue just medial to the thoracodorsal bundle and then running the index finger perpendicular to the course of the long thoracic nerve on the chest wall to identify the cordlike nerve as it moves under the finger. Once the nerve is identified, axillary tissue may be swept anteriorly away from the nerve by blunt dissection along the anterior serratus muscle; there are no significant vessels in this area.

The junction of the thoracodorsal bundle with the axillary vein is 1.5 to 2.0 cm medial to the point at which the axillary vein crosses the latissimus dorsi. The thoracodorsal vein enters the posterior surface of the axillary vein, and the nerve and the artery pass posterior to the axillary vein. Generally, one or two scapular veins branch off the axillary vein medial to the junction with the thoracodorsal vein. These are divided during the dissection and should not be confused with the thoracodorsal bundle.

The axillary vein and the thoracodorsal bundle having been identified, the pectoralis major is retracted medially at the level of the axillary vein, and the latissimus dorsi is retracted laterally to place tension on the thoracodorsal bundle. Once this exposure is achieved, the axillary fat and the nodes are cleared away superficial and medial to the thoracodorsal bundle to the level of the axillary vein. Superiorly, dissection proceeds medially along the axillary vein to the point where the fat containing level II nodes crosses the axillary vein. To improve exposure, the fascia overlying the level II extension of the axillary fat pad should be incised to release tension and expose the lipomale level II fat. As noted [*see Structures to Be Preserved, above*], the medial pectoral nerve passes onto the underside of the pectoralis major in this area and should be preserved. One or more small venous branches may pass inferiorly from the medial pectoral bundle; particular attention should be paid to preserving the nerve when ligating these venous branches.

The next step in the dissection is to reflect the axillary fat pad inferiorly by dividing the medial attachments of the axillary fat pad along the anterior serratus muscle. Care must be taken to preserve the long thoracic nerve. Because there are no significant vessels or structures in the tissue anterior to the long thoracic nerve, this tissue may be divided sharply, with small perforating vessels either tied or cauterized. Finally, the axillary fat is freed from the tail of the breast with the electrocautery or a knife.

There is no need to orient the axillary specimen for the pathologist, because treatment is not affected by the anatomic

level of node involvement. A closed suction drain is placed through a separate stab wound. (Some practitioners prefer not to place a drain and simply aspirate postoperative seromas as necessary.) A long-acting local anesthetic may be instilled into the axilla—a particularly helpful practice if the dissection was done as an outpatient procedure.

Breast Reconstruction

The vast majority of women undergoing a partial or complete mastectomy are candidates for breast reconstruction and should be offered a plastic surgery consultation before undergoing definitive surgical treatment. Reconstruction is covered by insurance and may be done either at the time of the oncologic surgery (immediate reconstruction) or as a delayed procedure (delayed reconstruction). Despite early concerns and debate, studies show that neither mode of reconstruction interferes with detection of recurrent disease nor does it significantly delay subsequent adjuvant therapy.

REPAIR OF PARTIAL MASTECTOMY DEFECTS (ONCOPLASTY)

Recently, there has been an increase in the proportion of breast cancer patients treated with partial mastectomy followed by radiation therapy, an approach referred to as BCT. This trend is in part attributable to increased mammographic screening that has led to the detection of earlier breast cancers and the use of neoadjuvant chemotherapy, where significant clinical responses can obviate the need for a traditional mastectomy. Alarming, 20 to 30% of patients who undergo BCT report having a poor cosmetic result in the treated breast.⁸⁹

The term *oncoplasty* has been used to describe techniques to improve the cosmesis of the breast after oncologic resection. Techniques integral to plastic surgery are often incorporated and include local tissue rearrangement, purse-string defect closure, breast reduction techniques, local pedicled flaps, and lower abdominal flaps.^{89,90} The ultimate goal is to obtain a natural-appearing breast with improved cosmesis compared to partial mastectomy alone.

REPAIR OF MASTECTOMY DEFECTS

Options for breast reconstruction continue to evolve and include, but are not limited to, implants with or without tissue expansion, the transverse rectus abdominis myocutaneous (TRAM) flap, the latissimus dorsi myocutaneous flap, and various other free flaps. Patient preference and lifestyle, the availability of suitable autologous tissue, and the demands imposed by additional cancer therapies are variables that can influence the timing and choice of the optimal reconstructive technique [*see Figure 13*].

If the need for postmastectomy radiation therapy is definite or unclear at the time of mastectomy (i.e., final pathology results are not available), a delayed reconstruction may be chosen because of an increased risk of complications related to the reconstructed breast. An expander is typically placed at the time of mastectomy to preserve the breast skin envelope, and the definitive reconstructive plan is formulated once the final pathologic results have become available and the radiation therapy has been completed.⁹¹

RECONSTRUCTION OPTIONS

Prosthetic Implants

The simplest method of reconstruction is to place a saline- or silicone-filled implant beneath the pectoralis major. However, even after SSM, the pectoralis major is usually so tight that expansion of this muscle and the overlying skin is necessary before an implant that matches the opposite breast can be inserted. A tissue expander is typically placed and serial expansions are performed on an outpatient basis until an appropriate-size breast pocket has been attained. The time required to complete the expansion process usually ranges from 3 to 6 months after mastectomy and is dependent mostly on the desired breast size, the thickness of the mastectomy skin flaps, and the patient's ability to tolerate the expansion.⁹² A second operative procedure is then required to exchange the expander for a permanent implant. The nipple-areolar complex is constructed at a later date. AlloDerm (LifeCell Corp., Branchburg, New Jersey) and Flex HD (MTF, Edison,

New Jersey) are acellular dermal matrices derived from human cadaver skin that may be sewn to the pectoralis muscle and the inframammary fold to reinforce the lower pole of the breast and enlarge the breast pocket so that it may accommodate a tissue expander or implant.⁹³ This measure may reduce postoperative pain and improve cosmesis, as well as facilitate immediate implant placement in smaller-breasted women. Porcine-derived dermal matrices are also available and may be used as an alternative to the aforementioned.

The major advantages of implant reconstruction are reduced operative time, faster recuperation, and a reasonably good cosmetic outcome. These advantages must be weighed against the fact that this method is a two-stage approach and that obtaining symmetry with the contralateral native breast can be difficult and often requires a mastopexy (breast lift) with or without an implant augmentation.⁹⁴ The cosmetic result may also deteriorate over time as a consequence of capsule formation or implant migration, resulting in replacement of the implant each decade.

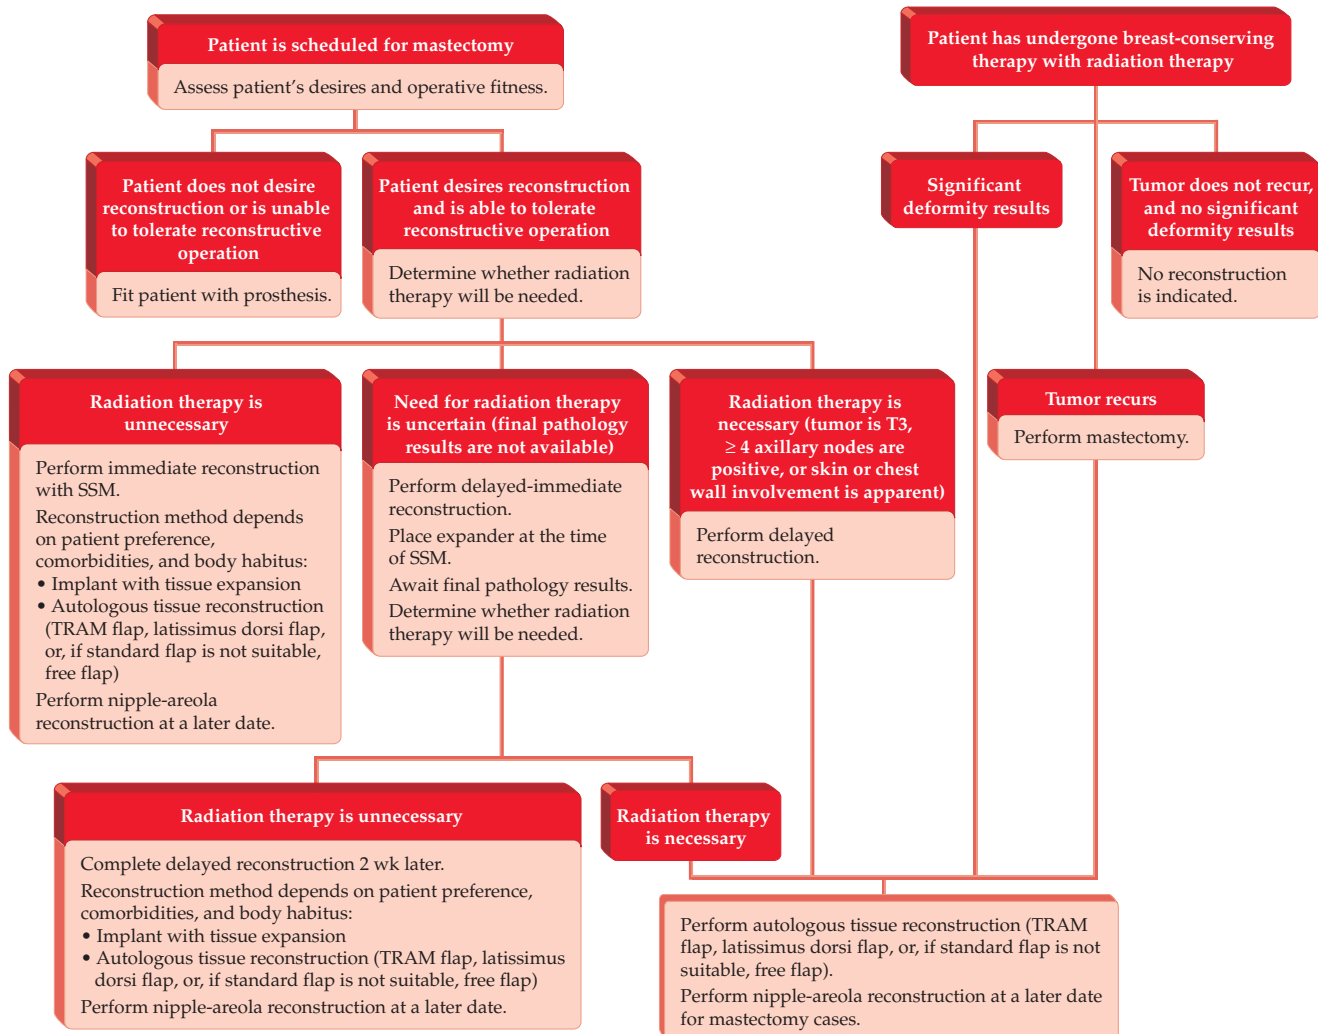

Figure 13 Algorithm outlining the major steps in breast reconstruction after mastectomy. SSM = skin-sparing mastectomy; TRAM = transverse rectus abdominis myocutaneous.

Autologous Tissue

An alternative approach to reconstruction that continues to evolve is the transfer of vascularized muscle, skin, fat, or a combination of these from a donor site to the mastectomy defect. The transferred tissue may be relocated either on a vascular pedicle or as a free tissue transfer requiring a microsurgical anastomosis. Although autologous tissue procedures can be lengthy and are associated with a longer recovery period, they often require fewer revision and symmetry procedures.⁹⁵ With autologous tissue reconstruction, it is possible to create a natural-appearing breast without the need for a breast implant, often sparing the patient a contralateral breast procedure to obtain symmetry.⁹⁴ The most commonly used pedicled myocutaneous flaps are the TRAM flap [see Figure 14] and the latissimus dorsi flap [see Figure 15]. Recent advances have led to the conception of perforator flaps such as the deep inferior epigastric perforator (DIEP) flap and the superficial inferior epigastric artery (SIEA) flap, which allow for safe and reliable tissue transfer with minimal donor-site morbidity.

The major advantage of autologous tissue reconstruction is that it generally yields a superior cosmetic result and provides variability in breast volume and shape⁹⁶; in addition, the reconstructed breast has a softer, more natural texture than a breast that has undergone implant reconstruction. The main drawbacks are the magnitude of the surgical procedure (involving both a prolonged operating time and longer inpatient hospitalization), the potential need for blood transfusion, and the morbidity related to the donor site. Smokers and patients with significant vascular disease may not be ideal candidates for autologous tissue reconstruction. Partial necrosis of the transferred flap may create firm areas; on rare occasions, complete necrosis and consequent loss of the flap can occur.

Pedicled myocutaneous flaps In a pedicled TRAM flap reconstruction, the contralateral rectus abdominis is transferred along with overlying skin and fat based on the superior epigastric vessels to create a breast mound. This procedure yields a flatter abdominal contour but calls for a long transverse abdominal incision and necessitates repositioning of the umbilicus. The major advantages of TRAM flap reconstruction are that it provides enough tissue to match most contralateral breasts and that it offers the option of performing bilateral TRAM flap procedures in healthy candidates who desire or require bilateral reconstruction. Patients who have undergone abdominal procedures that compromise the TRAM flap's vascular supply are not ideal candidates for TRAM reconstruction. Postoperative discomfort is greater with TRAM flap reconstruction than with other flap reconstructions because of the extent of the abdominal wall dissection and defect.

In a pedicled latissimus dorsi myocutaneous flap reconstruction, the ipsilateral latissimus dorsi is transferred along with overlying skin and fat based on the thoracodorsal vessels to create a breast mound. The operative technique for the latissimus dorsi flap reconstruction is complex, requiring intraoperative changes in patient position (unless the oncologic surgeon is willing to perform the mastectomy with the patient in a lateral decubitus position). Patients who have undergone irradiation of the breast, the chest wall, or the axilla (including irradiation of the thoracodorsal vessels) may not be eligible for this procedure. A major advantage of the latissimus dorsi flap is that its donor site is associated with less postoperative discomfort than the abdominal donor site of the TRAM flap. In addition, transfer of the latissimus dorsi results in substantially less functional impairment than transfer of the rectus abdominis. One major drawback is that in many women, the latissimus dorsi is not bulky enough to

Figure 14 Breast reconstruction after mastectomy: transverse rectus abdominis myocutaneous (TRAM) flap. (a) The infraumbilical flap is designed. The TRAM flap is tunneled subcutaneously into the chest wall cavity. Blood supply to the flap is maintained from the superior epigastric vessels of the rectus abdominis. (b) Subcutaneous fat and deepithelialized skin are positioned under the mastectomy flaps as needed to reconstruct the breast mound. (c) The fascia of the anterior rectus sheath is approximated to achieve tight closure of the abdominal wall defect and to prevent hernia formation. The umbilicus is sutured into its new position.

Figure 15 Breast reconstruction: latissimus dorsi flap Breast reconstruction after mastectomy: latissimus dorsi myocutaneous flap with submuscular implant. With this flap, addition of an implant is often required to provide the reconstructed breast with adequate volume and projection. (a) The myocutaneous flap is elevated; it is important to maintain the blood supply to the flap from the thoracodorsal vessels. The flap is tunneled subcutaneously to the mastectomy defect. (b) The latissimus dorsi is sutured to the pectoralis major and the skin of the inframammary fold so that the implant is completely covered by muscle.

Figure 16 Preoperative computed tomographic angiography of the inferior epigastric arterial system, the basis for free transverse rectus abdominis myocutaneous (TRAM), deep inferior epigastric perforator (DIEP), and superficial inferior epigastric artery (SIEA) flaps, used for autologous breast reconstruction.

provide symmetry with the contralateral breast; consequently, to match the size of the opposite breast, the flap must be supplemented with an implant. Thus, the drawback of the implant's limited life span is added to the drawbacks associated with autologous tissue reconstruction.

Free myocutaneous and perforator flaps Free-flap reconstruction options are used primarily when other autologous and implant reconstruction options are not available, do not provide sufficient tissue volume, or have failed. They are more complex procedures, requiring microvascular anastomoses, and carry a higher risk of total flap loss. Although, historically, the free TRAM flap and the free gluteal artery flap (GAP) have been the most often employed techniques, the introduction of perforator flaps (DIEP, SIEA, superior GAP, inferior GAP) has added options to the reconstructive surgeon's armamentarium. Preoperatively, CT angiography [see Figure 16] has replaced duplex ultrasonography as the gold standard for evaluation of donor vessel caliber and patency.⁹⁶ Perforator flaps are supplied by blood vessels that perforate through or around overlying muscles to vascularize the overlying skin and fat. During flap harvest, these perforators must be meticulously dissected free from the surrounding muscle, which is preserved intact and left in its natural position. The free tissue flap is then anastomosed to recipient vessels, and the donor site is closed without the need of additional support such as mesh or biologics.⁹⁷ Ideally, they provide adequate tissue for reconstruction without the level of donor-site morbidity seen with the free TRAM or other myocutaneous free flaps.⁹⁸ The disadvantages of perforator flaps include the considerable technical expertise and long operating time required, as well as the greater potential for flap loss (because these flaps have a more tenuous blood supply than the standard TRAM flap).

Financial Disclosures: None Reported.

6 LYMPHATIC MAPPING AND SENTINEL NODE BIOPSY

David W. Ollila, MD, FACS, Karyn B. Stitzenberg, MD, MPH, and Nancy Klauber-Demore, MD, FACS*

With an estimated 194,280 new cases in the United States in 2009, breast cancer is among the most common malignancies treated by US surgeons.¹ Meanwhile, the incidence of melanoma is rising faster than for all other solid malignancies. In 2009, there were an estimated 68,720 new cases of invasive melanoma in the United States.

Over the past 25 years, significant strides have been made in the management of these two diseases from the standpoint of both surgical and adjuvant therapy. For both diseases, the presence or absence of lymph node metastases is highly predictive of patient outcome and is the most important prognostic factor for disease recurrence and cancer-related mortality. As a result, nodal staging is a critical component of the staging workup and of treatment planning. The focus of this chapter is the role of nodal staging for both diseases.

No patient with tumor-free regional lymph nodes derives any therapeutic benefit from a complete regional lymphadenectomy. For patients with clinically negative nodal basins, the development of intraoperative lymphatic mapping and sentinel node (SN) biopsy has made it possible to map lymphatic pathway from a primary tumor to the initial draining node(s) (i.e., the SN or SNs) in the regional nodal basin. This is the lymph node most likely to harbor metastatic nodal disease, if any exists. It has been demonstrated in both breast cancer and melanoma that the pathologic status of the SN, when performed by an experienced team, is to be concordant with the pathologic status of the entire nodal basin. Integration of these techniques, along with increasingly detailed and sophisticated pathologic examination of the SN, into the surgical treatment of melanoma and breast cancer offers the potential for more conservative nodal basin operations, lower morbidity, and more accurate disease staging.

Lymphatic Mapping and SN Biopsy for Melanoma

RATIONALE

Assessment of Nodal Status

Approximately 20% of melanoma patients have nodal metastases at the time of diagnosis. The presence of lymph node metastases is the single most powerful predictor of recurrence and survival in melanoma patients. Five-year

survival is approximately 40% lower in patients who have lymph node metastases than in those who do not.² As a result, accurate nodal staging is important for stratifying patients into different risks groups that can be used to direct further therapy.

Elective Lymph Node Dissection

Until the early part of the 1990s, elective lymph node dissection (ELND) was the mainstay of the surgeon's armamentarium for nodal staging of melanoma patients. ELND is the complete surgical removal of the closest nodal basin in patients with clinically negative lymph nodes. In contrast, therapeutic lymph node dissection (TLND) is the complete surgical removal of the draining nodal basin known to have histopathologically confirmed nodal metastases. Three prospective, randomized trials failed to demonstrate better survival in melanoma patients treated with ELND than in patients undergoing wide local excision (WLE) alone as primary surgical therapy.³⁻⁵

With ELND offering no overall survival advantage, a more accurate method to identify the approximately 20% of melanoma patients who presented with nodal metastasis was needed. In the 1970s, Roth and colleagues were attempting to identify the nodal basin at risk by injecting colloidal gold around a patient's primary melanoma site.⁶ This was a very crude technique that identified only the basin at risk and not the specific node at risk. Alternative newer-generation radiopharmaceuticals and improved gamma detection devices were needed.

An alternative method of identifying the node at risk for harboring metastatic disease was first described by Wong and colleagues using a feline model.⁷ They demonstrated that a vital blue dye (Lymphazurin, Hirsch Industries, Inc., Richmond, VA) injected into the dermis of the cat would travel via the dermal lymphatics to the regional nodal basin.

The following year, in human melanoma patients, Morton and colleagues demonstrated the feasibility of lymphatic mapping and SN biopsy using vital blue dye injected.⁸ These investigators showed that the SN is the first node in the regional lymphatic basin into which the primary melanoma consistently drains (although not necessarily the closest to the primary lesion). They harvested the SN separately from the remainder of the regional nodes and found that the pathologic status of the SN was highly accurate at predicting the pathologic status of the entire nodal basin, which was also surgically removed in all of the patients studied. These findings suggested that melanoma patients could be accurately staged with procedures that were far less extensive than complete regional nodal dissections.

* The authors and editors gratefully acknowledge the contributions of the previous authors, Seth P. Harlow, MD, David N. Krag, MD, FACS, Douglas S. Reintgen, MD, FACS, Frederick L. Moffat Jr, MD, FACS, and Thomas G. Frazier, MD, FACS, to the development and writing of this chapter.

PREOPERATIVE EVALUATION

Selection of Patients

The risk of nodal metastases in any one individual melanoma patient depends on a number of factors, including primary tumor thickness, presence of ulceration, and mitotic rate.^{9,10}

SN biopsy is most likely to alter therapy in patients who have a significant risk of nodal metastases but a low risk of systemic disease. As a result, the subgroup of patients with intermediate-thickness melanomas (1.0 to 4.0 mm) is the group most likely to benefit from SN biopsy. In patients with melanomas between 0.76 and 1.0 mm thick, the risk of nodal metastasis is approximately 5 to 6%,^{11–16} and a balanced discussion should be held with the patient including other factors such as ulceration, mitotic rate greater than 1, male sex, and axial location.¹⁷ Patients with thin melanomas and multiple risk factors may be at high enough risk to warrant SN biopsy.

On the opposite end of the spectrum are patients with thick melanomas (> 4.0 mm). For these patients, the risk of systemic metastases is as high as 50 to 60%, whereas the risk of nodal metastases ranges from 40 to 50%. ELND was not recommended for such patients in the past because of this high risk of systemic disease. However, even among patients with thick melanomas, survival is better for those with negative nodes than for those with microscopic nodal disease.¹⁸ As a result, patients with thick melanomas and no obvious systemic metastases may benefit from SN biopsy to stage the nodal basin. This is particularly important if the presence of nodal metastases will change the adjuvant treatment plan from observation to active systemic therapy.

The available data suggest that lymphatic mapping is applicable to all primary body sites, including the head and neck (the most technically demanding sites).^{19,20} The best results are achieved with a combination mapping approach that employs both a vital blue dye and a radiocolloid. The procedure is associated with slightly higher false negative rates in patients with head and neck melanoma than in those with melanoma of the trunk or extremities (10% versus 1 to 2%). Nevertheless, the false negative rates with head and neck melanoma are still low enough to justify offering lymphatic mapping to patients.

Special Circumstances

The extent of any operation done at the primary site before SN biopsy may affect the success of the biopsy procedure. In patients who have had an appropriate 1 or 2 cm margin resection and then large areas of tissue undermining or have undergone reconstruction with a rotational flap or Z-plasty to close the oncologic resection defect, the normal lymphatic channels may be disrupted. Such disruption may render SN biopsy inaccurate. Nevertheless, there have been reports of SN biopsy being performed successfully after previous WLE.²¹ These patients may have more SNs in more regional nodal basins than patients in whom the primary tumor has not been resected with curative intent, but at present, there is no unequivocal evidence that previous WLE of the primary lesion increases the risk of postoperative nodal relapse.^{22,23}

Increasingly, surgeons are caring for patients who have undergone previous nodal surgery. Over time, patients develop alternate lymphatic drainage pathways after nodal surgery. Although localization rates tend to be lower under these circumstances, the accuracy of the SN for predicting the status of the nodal basin remains high.^{24,25} Preoperative lymphoscintigraphy is critical, even for breast cancer patients, because the altered lymphatic pathways may result in drainage to less common nodal basins. Because development of new drainage pathways takes time, accuracy is related to the amount of time that has elapsed since the first procedure. For patients in whom the previous nodal procedure was performed less than 6 months previously, the reliability of the SN is doubtful.

Breast cancer and melanoma are frequently diagnosed in women of childbearing age, so the safety of lymphatic mapping during pregnancy needs to be discussed. Sentinel lymphadenectomy generally requires general anesthesia, so the risks of surgery during pregnancy need to be considered. In addition, there are potential risks related specifically to the lymphatic mapping. Neither isosulfan blue dye nor methylene blue dye has been tested for safety during pregnancy. In the absence of data, it is recommended that these be avoided. Although radiation is teratogenic, studies suggest that the levels of radiation associated with lymphoscintigraphy are low and safe.^{26–28} No adverse events have been documented in reported case series to date.^{29,30}

OPERATIVE PLANNING: POSITIONING AND ANESTHESIA

Patients should be prepared to undergo wide excision of the primary melanoma site (if not previously performed) and SN biopsy during the same operative session. Depending on the location of the primary lesion, it may be possible to perform the two procedures with the patient in a single position; however, often the patient must be repositioned during the procedure to afford the surgeon adequate access to the different locations. The choice of anesthesia varies, depending on the size and location of the wide excision and the anatomic depth of the SNs. In very selected cases, local anesthesia may be appropriate, but for most lesions, general or regional anesthesia is preferable.

OPERATIVE TECHNIQUE

Although the technical details of lymphatic mapping and SN biopsy for melanoma vary from institution to institution, the reported results of the different approaches have been very similar. Proper performance of these procedures requires close collaboration between the nuclear medicine physician, the surgeon, and the pathologist, with each member playing a critical role in the process.

Step 1: Injection of Radiolabeled Tracer and Lymphoscintigraphy

On the day of the procedure, the patient reports to the nuclear medicine suite for injection of the radiolabeled tracer and preoperative lymphoscintigraphy. It is crucial to have a mechanism in place by which the location of the primary melanoma site can be reliably communicated to the nuclear radiologist. Some melanoma biopsy sites are difficult to locate, particularly if multiple skin biopsies have already been performed.

A radiolabeled agent is then selected; the most common choices are technetium-99m (^{99m}Tc)-labeled sulfur colloid (TSC) and ^{99m}Tc -labeled antimony trisulfide colloid (T-ATC). The dose of the tracer and the volume of the injectate are largely determined by the location and size of the primary tumor site but generally can be kept to 0.5 mCi or less and 1 mL or less, respectively. Injections are made intradermally around the circumference of the lesion or biopsy site, and dynamic scans are taken 5 to 10 minutes after injection. Although the location of the SN may be marked on the skin by the radiologist to assist the surgeon, this location may vary slightly with changes in patient position and should therefore be confirmed by the surgeon with the gamma probe in the operating room. To allow complete and accurate nodal staging, all regional basins at risk should be marked, along with any in-transit nodes that are identified [see Figure 1]. If there is no migration of TSC after approximately 60 to 90 minutes, then a second injection of filtered TSC is performed. If no migration occurs, the nuclear medicine physician communicates this directly with the operating surgeon.

The surgical procedure should be carried out no more than 6 to 8 hours after TSC injection. Activity in the SNs usually reaches its maximum 2 to 6 hours after injection; waiting longer to carry out the procedure may increase the labeling

of secondary nodes. There have, however, been several reports of SN procedures being accurately performed 16 to 24 hours after tracer injection.¹⁹ Because TSC is retained in the SN dendritic cells, the SNs can still be easily identified after 6 hours, whereas the radioactivity at the injection site and resultant background interference may be diminished because of the short half-life of technetium (6 hours).

Step 2: Intraoperative Lymphatic Mapping and Identification of SN

It is our practice to review the lymphoscintigram when the patient arrives in the preoperative holding area. For patients who had either ambiguous drainage or no drainage, we evaluate the patient with the gamma probe before deciding on positioning. Probe evaluation, whether performed in the preoperative holding area or in the operating room, begins by defining the diffusion zone around the primary tumor site, where SN identification is not possible. The area between this diffusion zone and the possible nodal drainage sites is then mapped for possible in-transit nodes by means of a systematic but expeditious evaluation for radioactive “hot spots.” The gamma probe is moved in a linear fashion between the diffusion zone and the nodal basin. It is then shifted medial or lateral to the previous line, and the process is repeated until the entire area is evaluated. The location of a radioactive hot spot is confirmed by identifying a discrete location where the radioactive counts are higher than the counts found in the tissue 1 to 2 cm more proximal to the injection site (the background skin count). The counts from the hot spot and the background are recorded. The hot-spot site is marked on the skin to allow more direct dissection to the SN.

Concomitant use of a vital blue dye is favored by many surgeons and is our preferred method. The blue dye is complementary to the radiolabeled tracer; the combination of the two marking agents improves the chances of identifying the SN and facilitates node retrieval. The blue dye is injected into the dermis immediately adjacent to the melanoma. For lesions on an extremity, the dye may be injected along the proximal margin of the lesion or biopsy site; for lesions on other areas, it should be injected circumferentially. The general recommendation is to wait 5 to 10 minutes after injecting the dye before initiating SN retrieval.

To minimize the dissection required for node resection, the incision for the SN biopsy should be made through the hot spot identified by the gamma probe. The incision should also be situated so that it can be incorporated into a longer incision should the finding of a positive SN necessitate performance of a TLND. The gamma probe is placed in a sterile sheath and used again after the incision is made to guide further dissection. If blue dye was used, the surgeon can visually follow the blue lymphatic channels to the blue-stained SN.

An SN is defined as either (1) all radioactive nodes with an ex vivo node to background ratio greater than 10:1, (2) a node that either is blue or clearly has a blue-stained lymphatic vessel entering it, or (3) a firm palpable node. When an SN is removed, the ex vivo radioactivity count in the node is recorded. This count is then used as a reference for determining which, if any, of the remaining nodes in that basin (some of which may be potential SNs) should be removed. In our

Figure 1 Lymphatic mapping and sentinel lymph node (SLN) biopsy for melanoma. In-transit nodal areas are identified in 5% of melanoma patients; this is the reason why preoperative lymphoscintigraphy is performed for primary sites on either the upper or the lower extremity. In a patient with a melanoma on the left hand (a), the injection site and the left arm are raised above the head, and cutaneous lymphatic flow into an epitrochlear node can be seen. This in-transit node then emits a lymphatic vessel flowing to the left axilla. By definition, the SLN is the first node in the chain that receives primary lymphatic flow. The epitrochlear node and any axillary nodes are nodes in series. Hence, the epitrochlear node is the SLN and thus is the only node that must be harvested. In a patient with a primary melanoma on the left flank (b), there are two separate afferent lymphatics, one leading to an SLN in the left axilla and the other leading to an in-transit node on the left flank. These are nodes in parallel in that they both receive primary lymphatic flow from the skin site. Hence, the two nodes are equally at risk for metastatic disease, and both are considered sentinel nodes and must be harvested.

view, if the radioactivity count in the hottest remaining node in the basin is less than 10% of the ex vivo count in the hottest SN, none of the remaining nodes should be considered SNs.^{19,31} Any nodes with radioactivity counts exceeding this 10% threshold, however, should be removed.

Once an SN is identified, it should be dissected out with as little trauma to the surrounding tissues as possible. Lymphatic channels to the node should be identified and either tied or clipped to reduce the risk of postoperative seroma formation. Because the gamma probe can localize SNs with great accuracy, routine dissection of motor nerves is not required; however, knowledge of the likely location of the motor nerves is critical for preventing inadvertent injury to these structures during dissection.

After SN removal, a final count of the SN biopsy bed is taken to document that all significantly radiolabeled nodes have been accounted for and removed. In addition, the tissues are examined for blue-stained lymphatic channels or lymph nodes regardless of radioactivity. (As noted, blue staining confers SN status even if the node is not radioactive.)

Firm tumor-involved nodes with obstructed afferent lymphatics may divert lymph flow to non-SNs, and such diversion is a significant cause of false negative SN biopsy results. Consequently, the final step is to palpate for grossly suspicious nodes. If grossly suspicious nodes are identified after all relevant SNs have been removed, the suspicious nodes should also be removed.

Step 3: Pathologic Evaluation of SN

The optimal extent of pathologic evaluation of SNs in patients with melanoma has been the subject of some debate. SN biopsy allows pathologists to focus their efforts on one node or a small number of nodes, and this focus has led to a process of ultrastaging. Several good methodology articles describing the handling and processing of SN are available in the literature.^{32,33} Our current institutional protocol has been published.³⁴ Briefly, the SN is bivalved and then serially sectioned at 1 to 2 mm section across both halves. The nodal sections are first evaluated with hematoxylin-eosin (H&E) stain. If no obvious metastases are identified, the immunohistochemical stains are applied, S-100 and MART-1. This enables the pathologist to identify tiny (less than 1 mm) deposits of metastatic melanoma.

COMPLICATIONS

Complications of SN biopsy are quite uncommon. Allergic reactions to the blue dyes occur in less than 1% of patients but can range in severity from mild urticaria to anaphylaxis; thus, the surgical team and the anesthesia team should always be prepared for this uncommon but potentially serious problem.^{35,36} In experienced hands, motor nerve injury is rare. In a series of 47 patients who had head and neck melanomas with SN drainage to the parotid region, there were no permanent injuries to the facial nerve when the SN was removed without formal nerve dissection.³⁷ Similar results have been reported for nodes in the posterior triangle of the neck and in the axilla. The incidence of wound complications is quite low (1.7% wound complication rate; 3.0% seroma rate), as is the incidence of postbiopsy lymphedema (0.7%). In the Sunbelt Melanoma Trial, the complication rate in 2,120 patients

undergoing SN biopsy was 4.6%, compared with 23.2% in 444 patients undergoing completion lymph node dissection (CLND).³⁸

OUTCOME EVALUATION

Ideally, level I evidence from a prospective, randomized, controlled trial would demonstrate that lymphatic mapping and SN biopsy are superior to close nodal observation as the treatment of choice for melanoma patients. The Multicenter Selective Lymphadenectomy Trial (MSLT-1; Donald Morton, principal investigator) was designed to compare WLE and SN biopsy to WLE and close observation in patients with intermediate-thickness melanomas. A detailed description of the trial has been published.³⁹ Briefly, all patients with intermediate-thickness melanomas eligible for the trial (Breslow thickness 1.2 to 3.5 mm) were randomized in a 60:40 ratio to WLE and SN biopsy or to WLE and watchful waiting. All patients with a tumor-involved SN went on to an immediate TLND. For patients in the watchful waiting arm, a delayed TLND was performed if clinically apparent, pathologically confirmed nodal disease was identified.

After the third interim analysis, the Data Safety Monitoring Board insisted that the data be released to the public because several secondary end points had been met. Most importantly, melanoma-specific survival in patients with nodal disease was improved for patients in the SN biopsy arm compared with watchful waiting. Patients with a tumor-involved SN who underwent immediate LND had a 5-year survival advantage compared with those in the watchful waiting arm who developed a nodal basin metastasis: 72.3% versus 52.4% (hazard ratio 0.51, 95% confidence interval 0.32 to 0.81, $p = .004$).³⁹ These results continue to hold up after the fourth interim analysis with 10-year survival advantage of 63.2% versus 36.5% ($p < .001$).⁴⁰

To date, the primary end point, improved overall survival, has not been met. Although this has led some critics to advocate abandoning SN biopsy in melanoma patients,⁴¹ several clarifications need to be emphasized. First, no lymph node-negative patient ever derives a survival benefit from undergoing nodal operation, whether ELND or SN biopsy. Given that the incidence of nodal metastases in patients with intermediate-thickness melanoma, as defined by the MSLT-1, would be expected to be around 20%, 80% of patients enrolled on the trial could not possibly derive a survival advantage. These patients who cannot benefit dilute the observed magnitude of effect for those who do benefit. Second, SN biopsy is not proposed as a therapeutic procedure but rather as a highly sophisticated staging procedure. On MSLT-1, the patients with a tumor-involved SN subsequently underwent a directed TLND. The results of MSLT-1 demonstrate a clear survival advantage in performing the TLND early in an association with a tumor-involved SN as opposed to later, when palpable lymphadenopathy is detected.

Lymphatic Mapping and SN Biopsy in Breast Cancer

RATIONALE: ASSESSMENT OF NODAL STATUS

In early breast cancer, as in melanoma, the pathologic status of the regional lymph nodes is the most important

predictor of outcome. The presence of regional lymph node metastases in breast cancer reduces 5-year survival by 28 to 40%.^{42,43} Prognostic factors related to primary tumor characteristics have consistently been shown to be inferior to nodal status as predictors of overall survival. In addition, axillary lymph node dissection in the setting of breast cancer is superior to observation and at least equivalent to irradiation for regional disease control in clinically node-negative patients.⁴⁴ There is some evidence that adequate regional disease control may confer a small survival benefit.⁴⁵

Invasive breast cancer has a relatively high rate of nodal metastasis in clinically node-negative patients. The risk of metastasis is clearly related to the size of the primary tumor, but it is significant (15% or higher) even in patients with early (T1a) lesions.^{46,47} The primary nodal drainage basin for the breast is the ipsilateral axilla; however, drainage to extra-axillary sites (e.g., the internal mammary lymph node chain, the supraclavicular nodes, and the intramammary nodes) is also reported. Other potential sites of lymphatic drainage notwithstanding, the recommended surgical procedure for evaluating the regional lymph nodes in clinically node-negative breast cancer patients has been level I and II axillary lymph node dissection (ALND). Such dissections are, however, associated with a significant risk of long-term morbidity, primarily related to the risk of lymphedema in the affected arm. For this reason, SN biopsy was developed and investigated as a possible substitute for standard ALND in the treatment of breast cancer patients with clinically uninvolved axillary lymph nodes.

PREOPERATIVE EVALUATION

Selection of Patients

All clinically node-negative patients with a diagnosis of invasive breast cancer are potential candidates for SN biopsy. Ideal candidates are those patients with unifocal lesions less than 5 cm in greatest dimension who have no history of previous axillary surgery or previous cancer treatment. Performing an SN biopsy after a previous excisional biopsy is technically feasible. Patients who have undergone extensive previous breast procedures (e.g., breast reduction, placement of breast implants, or multiple open biopsies) may have significant alterations in the lymphatic pathways; however, accurate identification of the SN can still be accomplished with proper planning of the injection sites. Patients with multifocal tumors or multicentric breast cancers also require thoughtful planning of the injection sites, although there is some evidence suggesting that using periareolar injection sites may allow the procedure to be performed accurately in patients with multifocal disease.⁴⁸ For patients who will be undergoing mastectomy with immediate breast reconstruction, performing SN biopsy as an outpatient procedure prior to the planned mastectomy may facilitate surgical planning depending on the need for postmastectomy radiation or ALND.⁴⁹ However, the false negative rate of SN biopsy may be higher in cases with large additive tumor burden.⁵⁰

For patients who present with inflammatory breast carcinoma or who present with palpable adenopathy and pathologically confirmed metastatic nodal disease, there is absolutely no role for SN biopsy at the time of presentation. The role of SN biopsy in patients who present with large breast cancers and are scheduled to receive neoadjuvant

chemotherapy is highly controversial. Several recent studies have shown a low false negative rate for patients with T3 tumors who have an SN procedure prior to neoadjuvant chemotherapy,^{51–55} as well as those authors advocating the procedure after the neoadjuvant chemotherapy.^{56–58} Several good reviews of the controversy are published.^{59–61} The remainder of this chapter deals with patients who present with unifocal, T1 or T2, clinically node-negative breast cancer.

OPERATIVE PLANNING: POSITIONING AND ANESTHESIA

Patients should be placed in the supine position, with all potential nodal sites within the operative field. Although SN biopsy may be performed with the patient under local anesthesia, we favor general anesthesia for this procedure, particularly when it is done in conjunction with the breast excision.

OPERATIVE TECHNIQUE

Step 1: Injection of Radiolabeled Tracer and Lymphoscintigraphy

In the United States, the radiocolloid most commonly employed for SN biopsy in breast cancer patients is TSC, which may be used either unfiltered or filtered (< 220 nm). The ^{99m}Tc dose generally ranges from 0.45 to 1.0 mCi, and the injectate volume ranges from 4 to 8 mL. Several routes of tracer injection have been investigated for SN biopsy in breast cancer patients, primarily in response to the difficulties sometimes associated with peritumoral injection (e.g., delayed tracer uptake and wide diffusion zones that can overlap the nodal basins). These routes include intradermal or subdermal injection in the area overlying the tumor, subareolar injection, and periareolar injection. The rationale for the development of these alternatives is that there is significant overlap between the lymphatic vessels of the breast skin and those of the breast parenchyma. Multiple studies have confirmed that the use of these injection routes yields high localization rates and results in accurate removal of SNs that reflect the pathologic nodal status of individual patients. A notable deficiency of these techniques, however, has been the low reported rate of tracer migration to nodes outside the axilla, particularly to the internal mammary lymph node chain. This result is thought to be attributable to a unique set of lymphatic channels deep in the breast parenchyma, separate from the overlying skin, that drain to the internal mammary chain.

The various tracer injection methods have not been directly compared; thus, at present, the optimal route of injection can be inferred only by comparing studies from different institutions. The potential importance of the extra-axillary sites is not entirely clear, but it appears that these sites may be the sole locations of metastatic disease in as many as 20% of the node-positive patients from whom they are removed.^{62,63} Most patients in whom SNs are found outside the axilla have additional SNs in the axillary basin.

A thorough literature review on the use of different routes of injection and the associated rates of SN localization by nodal basin, node positivity rates, and false negative rates has been performed. This review included those studies in which a radiolabeled tracer was used for SN identification (either by lymphoscintigraphy or by intraoperative gamma

probe localization) and in which the location of the SN basins and the pathologic status of the SNs could be ascertained. The results of previous reviews of almost 9,000 patients indicated that all of the approaches have acceptable SN retrieval rates but that the rates are slightly higher with the more superficial ones (i.e., the dermal, subareolar, and periareolar techniques).^{62,64–67} There are, however, significant differences in the locations of the SN basins identified with the different methods: with the superficial injection techniques, drainage is essentially confined to the axillary basin, whereas with the deeper injection techniques, as many as 22% of patients are found to have nodal basins outside the axilla. Approximately 16 to 21% of the extra-axillary SNs will be found to have metastatic disease if removed. The clinical ramifications of these findings are that some patients may be understaged if the extra-axillary sites are not evaluated, and such understaging may affect the recommendations for systemic adjuvant therapy.

Whether the breast cancer is palpable or nonpalpable, we prefer that the injection is guided by ultrasonographic evidence. If an excisional biopsy was previously performed, the tracer should be injected into the breast parenchyma rather than into the biopsy cavity; it will not diffuse out of the cavity. This is also best done under ultrasonographic guidance. In addition, injections should not be made into the retromammary fat or the pectoral fascia, because doing so would lead to wide diffusion of tracer throughout the chest area, which would make nodal identification very difficult.

In breast cancer patients, the timing of SN biopsy after tracer injection is not of critical importance. Good results have been obtained with injection-to-biopsy intervals ranging from 30 minutes to 24 hours. The usual recommendation is to wait 1 to 2 hours.

Step 2: Intraoperative Lymphatic Mapping and Removal of SN

Once the patient is asleep, the vital blue dye (Lymphazurin) is injected either peritumorally, into the parenchyma surrounding an excisional biopsy, intradermally, or subareolarly depending on surgeon preference. The breast is gently massaged for 5 to 10 minutes to enhance transport of the dye to the SNs. Our approach begins by performing a primary survey of the potential nodal sites with the handheld gamma detector. Using one of the commercially available handheld gamma probes, an axillary hot spot is identified, and then a small incision is made. The gamma probe, sterile sheathed, is inserted into the wound and guides the dissection to the radioactive node(s). During the dissection, the surgeon looks for blue-stained lymphatic channels and nodes [see Figure 2]. Most of the time, the radiocolloid and the vital blue dye identify the same SNs. The SNs are then carefully removed, and the lymphatic vessels entering them are tied or clipped off whenever possible.

An SN is defined as either (1) all radioactive nodes with an ex vivo node to background ratio greater than 10:1, (2) a node that either is stained blue or clearly has a blue-stained lymphatic vessel entering it, or (3) a firm palpable node. When an SN is removed, the ex vivo radioactivity count in the node is recorded. This count is then used as a reference for determining which, if any, of the remaining nodes in that

Figure 2 Lymphatic mapping and sentinel node (SN) biopsy for breast cancer. A small incision is made in the axilla on the basis of the hot-spot location. The SNs identified are both radioactive and stained blue.

basin (some of which may be potential SNs) should be removed. In our view, if the radioactivity count in the hottest remaining node in the basin is less than 10% of the ex vivo count in the hottest SN, none of the remaining nodes should be considered SNs, and none should be removed.⁶⁷ Any nodes whose radioactivity counts exceed this 10% threshold, however, should be removed.

A final count of the SN biopsy bed is then taken to document that all significantly radiolabeled SNs have been accounted for and removed. In addition, the tissues are examined for blue-stained lymphatic channels or lymph nodes regardless of radioactivity; as noted, blue staining confers SN status even if the node is not radioactive. Finally, when it appears that all relevant SNs have been removed, as confirmed by the final bed count, the tissues are palpated for grossly suspicious nodes. Firm tumor-involved nodes with obstructed afferent lymphatics may divert lymph flow to non-SNs, and such diversion is a significant cause of false negative SN biopsy results.

Once an SN is identified, it should be dissected out with as little trauma to the surrounding tissues as possible. Lymphatic channels to the node should be identified and either tied or clipped to reduce the risk of postoperative seroma formation. Because the gamma probe can localize SNs with great accuracy, routine dissection of motor nerves is not required; however, knowledge of the likely location of the motor nerves is critical for preventing inadvertent injury to these structures during dissection.

Step 3: Pathologic Evaluation of SN

Pathologic SN evaluation in breast cancer patients has two main aspects. The first is intraoperative evaluation of the SN when the pathologic status of the node is being used to determine the need for ALND; the second is permanent evaluation of the nodes to determine whether micrometastatic disease is present. Both have conflicting views in the literature.

Two techniques are commonly employed for intraoperative evaluation of SNs: frozen-section analysis and touch-imprint cytology. Frozen-section histopathology is available in most hospitals, and all surgical pathologists have some experience

with it. This technique has a drawback, however, in that it sometimes uses up a large portion of the SN, leaving a remnant that is insufficient for permanent paraffin-embedded sections. In addition, the sectioning of radioactive nodes on a cryostat raises radiation safety issues for the pathologists.

Studies of frozen-section techniques of evaluating SNs for metastatic breast cancer report false negative rates of 27 and 32%.^{64,68} When 60 frozen sections are made from each SN, the false negative rate can be reduced to about 5%,^{64,69} but at the cost of 45 to 60 minutes of operating time and loss of tissues for permanent histopathologic evaluation. Frozen section is far more effective in detecting macrometastatic disease (sensitivity 92%) than micrometastatic disease (sensitivity 17%), and the volume of nodal metastases is highly correlated with tumor size.⁷⁰ In comparison, touch-imprint cytology consumes much less time and tissue, is far more accurate (false negative rate 0.8%),⁷¹ and does not contaminate the cryostat. It has also been applied to the evaluation of lumpectomy margins [see Figure 3]. The chief limitation of the touch-imprint method is that for optimal results, it requires a pathologist who is highly skilled in the cytologic evaluation of lymph nodes. Some centers use rapid immunohistochemical (IHC) analysis for cytokeratin staining to detect tumor cells in touch-imprint or frozen-section specimens, anticipating that detection of such cells can thereby be improved, particularly in patients with invasive lobular or well-differentiated ductal carcinomas.

The optimal extent of pathologic evaluation of SNs in patients with breast cancer has been the subject of some debate. SN biopsy allows pathologists to focus their efforts on one node or a small number of nodes, and this focus has led to a process of ultrastaging. Several good methodology articles describing the handling and processing of SN are available in the literature.^{32,33} Our current institutional protocol has been published previously.³⁴ Briefly, the SN is bivalved

and then serially sectioned at 1 to 2 mm section across both halves. The nodal sections are first evaluated with H&E stain. In 1999, the College of American Pathologists issued a consensus statement recommending that the staging of SNs be based on routine histologic evaluation of the nodes cut at approximately 2 mm intervals.⁷² Routine use of cytokeratin IHC staining should not be adopted as standard until its significance is demonstrated in clinical trials.

COMPLICATIONS

The complications of SN biopsy in breast cancer patients are similar to those seen in melanoma patients.⁷³ There is a minor (< 1%) risk of allergic reactions to the blue dye.⁷⁴ There is a small risk of sensory or motor nerve injury or lymphedema whenever an axillary node procedure is performed; this risk is substantially reduced, although not entirely eliminated, with SN biopsy.⁷⁵ With an internal mammary SN biopsy, there is a risk of pneumothorax from unintended opening of the parietal pleura. This risk is very small with careful technique, however, and the problem can almost always be corrected by closing the wound around a rubber catheter inserted through a small stab incision and removing it at the end of a positive pressure breath given by the anesthesiologist. Surgical site infections occur in fewer than 1% of cases, and small seromas occur in about 10%.

OUTCOME EVALUATION

The first report of SN biopsy in breast cancer, published in 1993, described the use of the gamma probe localization technique for SN identification.⁷⁶ A second report, published the following year, described the use of the vital blue dye technique for SN identification.⁷⁷ Since these initial feasibility reports, many single-center and multicenter studies have been published that achieved remarkably similar results using either or both of these techniques.

The early studies of SN biopsy tended to use either a radio-labeled tracer or a vital blue dye alone. The first trial in which the two agents were used together was published in 1996.⁶⁵ This study documented an improvement in SN localization and a 0% false negative rate, albeit in a small series of patients. Subsequent multicenter trials incorporating larger study groups yielded more reliable indications of the applicability of these techniques to the overall surgical community. In one such study, surgeons from 11 centers performed SN biopsies and confirmatory axillary dissection in clinically node-negative patients with invasive breast cancer.⁶⁶ The overall success rate for identifying and removing an SN was 93%, the pathologic accuracy rate for predicting the presence of nodal metastases from the SNs removed was 97%, and the pathologic false negative rate was 11.4%. A subsequent multicenter trial, using a combination of blue dye staining and the gamma probe technique in most patients, reported an SN retrieval rate of 88% and a pathologic false negative rate of 7.2%.⁶⁷ A third trial, using the gamma probe technique, reported an SN retrieval rate of 87% and a pathologic false negative rate of 13%.⁷⁸ A fourth trial, using both blue dye staining and the gamma probe technique, reported an SN retrieval rate of 86% and a pathologic false negative rate of 4%.⁷⁹

To evaluate the true efficacy of a new technology, a prospective trial needs to be performed, and the first one completed was by Veronesi and colleagues.⁸⁰ In this trial, 516

Figure 3 Lymphatic mapping and sentinel node biopsy for breast cancer. In touch-imprint cytology, slides are touched to tissue from a “hot” specimen, and cells on the section or the margin are exfoliated onto the slide for cytologic preparation. Shown are (a) permanent histology of an infiltrating ductal carcinoma extending down to an inked margin and (b) a touch preparation demonstrating bizarre malignant cells from the sampling of the margin. The advantages of this technique are that the entire margin can be sampled and that tissue is not lost in the cryostat.

evaluable patients were randomly assigned to undergo either SN biopsy with confirmatory axillary dissection (257 patients) or SN biopsy with axillary dissection done only if the biopsy yielded positive results (259 patients). At a median follow-up point of 46 months, no significant survival differences were reported, and there were no regional nodal recurrences in either arm. Admittedly, the study size was small and the follow-up relatively short, but still there was no significance in axillary failure in patients who received only an SN biopsy.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) undertook a trial very similar to that of the Milan group, NSABP B-32. Breast cancer patients with clinically node-negative axillae were randomized to undergo SN biopsy with mandatory ALND or SN biopsy with ALND if the SN revealed metastatic breast cancer.⁸¹ Between 1999 and 2004, 5,611 patients were accrued and randomized. The technical details have been published⁸¹; previously, the SN identification on the trial was 97% and the false-negative rate was 9.7%, very consistent with some of the early breast SN reports. At the 2010 meeting of the American Society of Clinical Oncology (ASCO 2010), Krag and colleagues stated for the first time that there was no difference in overall survival, disease-free survival, or locoregional recurrences, thus providing level I evidence that the SN biopsy is an accurate and safe alternative to routine ALND in clinically node-negative breast cancer patients.⁸²

The American College of Surgeons Oncology Group (ACOSOG) undertook an SN trial designed to evaluate the incidence and prognostic significance of SN and bone marrow micrometastases in patients with early-stage breast cancer. ACOSOG Z0010 was a phase II trial in which all patients enrolled underwent a SN biopsy and bilateral iliac crest bone marrow aspirates. If the SNs were negative by H&E stain, then they were submitted to the central laboratory for IHC stains. From April 1999 through May 2003, 5,539 patients were enrolled. At ASCO 2010, Cote and colleagues presented for the first time the unblinded SN IHC results.⁸³ There was no difference in overall survival in patients with IHC-detected metastases compared with tumor-free SN (95.1% versus 95.8%, $p = .53$). Thus, the routine examination of SN with IHC in patients with invasive ductal carcinoma should not be performed.

The advent of the SN has reopened the debate regarding the impact of ALND on overall survival. One of the earliest NSABP studies, B-04, randomized patients to either radical mastectomy, total mastectomy with delayed ALND if necessary, or total mastectomy and radiotherapy.⁴⁴ There was no overall survival difference between the three arms of the trial, but the trial was not powered to detect a small survival advantage. Patients receiving an ALND appeared to have improved the locoregional recurrence rate.

The question in the SN era remains: in patients with H&E-detected metastases, what, if anything, should be done to the remainder of the axillary nodes? Two prospective, randomized trials were designed to answer this very important question. The first is the European Organisation for Research and Treatment of Cancer (EORTC) AMAROS (after mapping of the axilla: radiotherapy or surgery) trial in which patients with an H&E-detected SN metastasis were randomized to axillary radiation versus a completion ALND. The trial finished accrual in 2008 but, because of a lower than expected event rate, had to reopen to accrual. The other important trial is ACOSOG Z0011, in which patients with H&E-detected metastases were randomized to completion ALND or observation. At ASCO 2010, Giuliano and colleagues, for the first time, stated that there was no difference in overall survival between the two groups (completion ALND 91.9% versus observation 92.5%) or disease-free survival (82.2% versus 83.8%, $p = .13$).⁸⁴ Thus, in a large phase III trial, albeit underpowered, there is not even a trend toward a survival advantage in patients receiving ALND. Routine ALND following a positive SN adds nothing to the patient's overall survival.

Radiation Exposure Guidelines and Policies

The amount and type of radioactivity injected in the course of lymphatic mapping and SN biopsy are relatively limited. Typically, from 0.4 to 1.2 mCi of ^{99m}Tc is injected. This agent is a pure gamma emitter with a short half-life (6 hours); thus, the risks of potentially harmful beta radiation are avoided. The total radiation dose used is quite small—only about 5% of that used in common nuclear scanning techniques (e.g., bone scans). It has been estimated that a maximum of 0.45 Gy could be absorbed at the injection site. Of hospital workers, the surgeon is exposed to the highest levels of radiation. A study from Walter Reed Army Medical Center found that the hands of surgeons performing lymphatic mapping and SN biopsy were exposed to an average of 9.4 ± 3.6 mrem per operation.⁸⁵ Therefore, on the basis of skin dosage recommendations set by the Nuclear Regulatory Commission, a surgeon would have to perform more than 5,000 SN procedures a year to incur more than the minimal level of risk.

The low risk notwithstanding, proper handling of radioactive specimens is recommended. All such specimens should be handled as little as possible for at least 24 to 48 hours and should be appropriately labeled. Physicians performing these procedures should develop guidelines for handling and processing specimens in accordance with their institution's radiation safety policies.

7 EVOLVING MOLECULAR THERAPEUTICS AND THEIR APPLICATIONS TO SURGICAL ONCOLOGY

Melissa Heffler, MD, Vita Golubovskaya, PhD, and Kelli Bullard Dunn, MD, FACS, FACRS

Despite advances in both medical and surgical therapy for cancer, the majority of cancer deaths result from metastasis. Traditionally, chemotherapy has been the mainstay of therapy for systemic disease. However, even the most effective chemotherapeutic agents are rarely curative. Moreover, toxicity is common and can be debilitating and dose limiting. It has proven difficult to find an agent that is toxic to cancer cells but does not in some way damage healthy cells. This treatment paradox has prompted a revolution in drug development. Increasingly, research efforts are focusing on the development of agents that target molecules that are specific to tumor cells. The ability of cancer cells to resist apoptosis, proliferate unchecked, and detach and metastasize results from activation and dysregulation of complex signaling cascades that in normal cells are controlled by intrinsic checkpoints and regulatory processes. Better understanding of these pathways, and of their checks and balances, has led to the development of agents that specifically target these processes in tumor cells. Agents are generally classified based on mechanism of action; however, overlap exists, and class lines are often blurred. The following summary describes historic targeted therapies that have laid the groundwork for current investigations and outlines current breakthroughs that are revolutionizing the way cancer is treated. The ultimate goal of molecular therapeutics is to develop agents that are lethal only to tumor cells, that maintain efficacy without developing resistance, and that possess acceptable toxicities that make them well tolerated by patients.

Tyrosine Kinase Inhibitors

BIOCHEMICAL RATIONALE

Tyrosine kinases (TKs) are enzymatic proteins that catalyze the phosphorylation and activation of other signaling proteins.¹ As their name implies, the target of these kinases is the tyrosine residue on a variety of proteins. TKs have long been known to play a role in cancer progression, and as such, inhibition of TKs has been at the forefront of targeted cancer therapy.

TKs are classified as either receptor or nonreceptor kinases. Fifty-eight membrane-spanning receptor tyrosine kinases (RTKs) have been identified.² Structurally, the lipophilic transmembrane domain is flanked by an immunoglobulin-like, ligand-binding extracellular head and an intracellular

tyrosine autophosphorylating carboxy-terminal tail. The majority of RTKs function in pairs, and activation induces dimerization [see Figure 1].^{1,3,4} Dimerization then triggers a phosphorylation cascade involving the cytosolic non-RTKs [see Figure 2]. These non-RTKs relay intracellular signals by additional protein phosphorylation.⁴ Many processes involved in tumor progression and metastasis, including proliferation, angiogenesis, migration, and cell survival, are influenced by dimerization, autophosphorylation, and the resulting downstream signal cascade.^{1,3} Although these processes are necessary for normal cell turnover, mutations can alter the expression or activation of TKs and thereby lead to uncontrolled activation in cancer cells.⁵ To date, the 58 RTKs that have been described are classified into over 20 families based on molecular structure and the sequence of the kinase domain.^{2,5,6} Of these, approximately 30% have been found to be either mutated or unregulated in cancer.⁵ Several RTKs are now known to play important roles in tumorigenesis and have become effective therapeutic targets. For example, c-kit is unregulated in gastrointestinal stromal tumors (GISTs) and acute myelogenous leukemia (AML), HER-2 is elevated in breast cancer, and RET is altered in the multiple endocrine neoplasia (MEN) disorders.⁵ These and other RTKs, therefore, provide potential targets for molecular therapeutics.

TYROSINE KINASE INHIBITORS

Delineating the role of TKs in tumorigenic processes such as invasion, angiogenesis, and proliferation prompted the development of several tyrosine kinase inhibitors (TKIs) that target either the receptor or the ligand that promotes the downstream signal cascade.¹ The resulting flood of TKIs has been variably classified by the target receptor or ligand, the signaling pathway affected, or their molecular structure. For the purposes of this review, TKIs are classified based on molecular structure: (1) monoclonal antibodies, (2) small molecule kinase inhibitors, and (3) multitargeted kinase inhibitors [see Table 1].

Monoclonal Antibodies

TKIs were first introduced to the anticancer armamentarium with the development of imatinib mesylate for the treatment of chronic myelogenous leukemia (CML), and this monoclonal antibody revolutionized therapy for this disease. The majority of patients with CML possess the t(9;22) translocation mutation (Philadelphia chromosome) that fuses the

Figure 1 Activation of a receptor tyrosine kinase induces dimerization and downstream phosphorylation of nonreceptor tyrosine kinases. Major signaling cascades include the RAS/RAF/MAPK pathway, MEK pathway, and PI₃ kinase/AKT pathway. Adapted with permission from Zhu Y, Parada LF. The molecular and genetic basis of neurological tumours. *Nat Rev Cancer* 2002;2:616–26. EGFR= epidermal growth factor receptor; ERK= extracellular signal-related kinase; GAP= GTPase-activating proteins; GEF= guanosine exchange factors; MEK= mitogen-activated protein kinase; NF1= neurofibromin gene; PDGFR= platelet-derived growth factor receptor; PI3K= phosphatidylinositol-3 kinase.

Abl TK to the *Bcr* gene on chromosome 22.^{1,7} Transcription and translation of this mutation produce two TKs, p190 and p210, both of which are involved in hematopoietic stem cell proliferation and inhibition of apoptosis.¹ Imatinib blocks the adenosine triphosphate (ATP)-binding site on these proteins, hindering activation and downstream signaling. In clinical trials, this early TKI improved long-term survival in CML by prolonging periods of remission and has been an effective treatment modality for both newly diagnosed patients and those who have failed interferon-alfa therapy.⁸

The success of imatinib in the treatment of CML raised the question of whether this agent might be useful for treating solid tumors. The recognition that imatinib also inhibits the c-kit and platelet-derived growth factor receptor (PDGFR) TKs led to trials treating tumors with mutations in these molecules.⁹ For example, GISTs are well known to express c-kit, and imatinib has been highly successful in treating these

tumors. Currently, there are several clinical trials designed to test the efficacy of imatinib in other solid tumors, including colorectal cancer, ovarian cancer, prostate cancer, and thyroid cancer.¹⁰ Nevertheless, despite successes with this agent, prolonged use of imatinib has resulted in the development of resistant tumors. The most common mechanism of resistance appears to involve mutations in the kinase domain of bcr-abl, which then prevent binding of the drug.¹¹ As a result, current research is focusing on overcoming this limitation.

Another RTK that has been identified as a target for monoclonal antibody inhibition is epidermal growth factor receptor 2 (EGFR2, ErbB2), also known as human epidermal receptor 2 (HER-2).¹² This RTK can bind a wide array of growth factors, thereby inducing dimerization and stimulating downstream activation of either the RAS/MAPK, PI₃ kinase/Akt/mTOR, or other signaling pathways, which promote cell proliferation and migration and inhibit apoptosis.^{12,13} HER-2

Figure 2 Regulation of the cell cycle involves a highly complex sequence of events. The interaction of cyclin-dependent kinases (CdKs) and cyclins determines progression through different phases of the cell cycle. Adapted from SABiosciences. Cyclins and cell cycle regulation. Available at: www.sabiosciences.com (accessed October 2010).

is overexpressed in many malignancies, and between 20 and 30% of advanced breast cancers express this receptor.^{12,14} Trastuzumab is a humanized monoclonal antibody that inhibits activation of the HER-2 receptor by binding to the extracellular domain and blunting the activation of downstream signaling.¹² In addition, trastuzumab has been shown to affect breast cancer cells by inducing cell cycle arrest at G₁ via upregulation and translocation of p27 from cytosol to nuclei.^{15,16} These findings have led to clinical use of this drug for treating HER-2-positive breast cancer.

Trastuzumab has demonstrated efficacy against both early- and late-stage breast cancer and is currently the standard of care for HER-2-positive tumors.^{17,18} This agent was first used as adjuvant therapy for node-positive or advanced node-negative breast cancer with *HER-2* gene amplification. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31 and North Central Cancer Treatment Group (NCCTG) N9831 trials, trastuzumab was studied as a conjugate to the established treatment regimen of doxorubicin and cyclophosphamide plus paclitaxel.¹⁹ The Herceptin

Adjuvant (HERA) and Breast Cancer International Research Group (BCIRG) 006 trials then examined the efficacy of adjuvant trastuzumab for 1 or 2 years following different chemotherapy regimens (HERA) or as an addition to the regimen of anthracycline, cyclophosphamide, and docetaxal (BCIRG 006).²⁰ In all four trials, both disease-free survival and overall survival were improved in the groups that received trastuzumab. In addition, patients who received trastuzumab developed fewer metastases and had lower mortality compared with patients who received chemotherapy alone. Unfortunately, side effects observed in these studies and attributed to trastuzumab treatment were congestive heart failure and a measurable decline in left ventricular ejection fraction.^{19,20} Further investigation revealed that the risk of cardiac failure was greatest in patients who received anthracycline, and although there is evidence that this untoward effect was curtailed with the concomitant administration of epirubicin, it remains a real concern for many patients and physicians.²¹ Thus, trastuzumab should not be given with anthracycline, and close monitoring of cardiac function is recommended.

Although trastuzumab has traditionally been administered in conjunction with chemotherapy in advanced HER-2-positive disease, more recent work has focused on using this drug as a single agent in early disease in an effort to delay the use of other, more toxic chemotherapy.¹⁷ In addition, the recent phase III Trastuzumab for Gastric Cancer (ToGA) trial has suggested that trastuzumab may be a reasonable adjunct to capecitabine and cisplatin or 5-fluorouracil (5-FU) and cisplatin for patients with HER-2-positive gastric or gastroesophageal junction cancer. Patients who received trastuzumab experienced 13.8-month median overall survival compared with 11.1 months for those receiving chemotherapy alone, decreasing the rate of death by 26%.^{22,23} Trials are also under way to test the efficacy of trastuzumab in combination with other targeted therapies. For example, trastuzumab-DM1 is a combination of the monoclonal antibody and the maytansine derivative DM1, a drug that interferes with microtubule formation. Preclinical studies demonstrate efficacy in lapatinib and trastuzumab-refractory breast cancer cells, and this combination is currently in phase II clinical trials for the treatment of breast cancer.^{24,25} Preliminary data show an approximately 40% overall response rate in metastatic disease after 6 months.^{26,27}

Like trastuzumab, cetuximab is a monoclonal antibody that targets EGFRs by binding to the extracellular domain.^{3,28} The development of this drug began with the identification of a murine monoclonal antibody (called 225) that could bind EGFR and inhibit activation of the intracellular TK domain of the receptor. The downstream effects of 225 included increased apoptosis and cell cycle arrest in G₁.²⁹ Experimental data were promising; however, concern about the use of a mouse monoclonal antibody in the human population and the potential for antimouse antibody response prompted chimerization of the antibody with human IgG1.^{30,31} The resulting chimeric antibody (C225, cetuximab) performed better than the original 225 antibody in inhibiting tumor growth in vivo.^{31,32} In addition, early studies demonstrated the efficacy of cetuximab in improving progression-free survival and overall response rate in metastatic colorectal tumors that had developed resistance to chemotherapeutic agents such as irinotecan.^{3,33} Moreover, patients with metastatic colorectal cancer refractory to oxaliplatin and fluoropyrimidine (5-FU) experienced prolonged progression-free survival when cetuximab was given in conjunction with irinotecan compared with irinotecan alone. These results established the combination regimen as a standard of care for refractory metastatic colorectal cancer.³ In 2004, cetuximab either in combination with irinotecan or as a single agent was approved by the Food and Drug Administration (FDA) for the treatment of metastatic colorectal cancers that express EGFR and are refractory to irinotecan- or oxaliplatin-based therapies.^{3,34,35}

As cetuximab was increasingly used to treat refractory metastatic colorectal cancer, it became clear that this agent is most effective in a subset of patients.^{33,36–38} Specifically, tumors possessing a mutation in the *K-ras* gene responded poorly to cetuximab, whereas tumors with wild-type *K-ras* responded well.^{39–41} The consensus that *K-ras* status is a predictive marker for response to cetuximab therapy has led to current recommendations that patients be tested for the mutation prior to the initiation of treatment.^{42,43}

In 2001, Shin and colleagues studied the combined effect of cetuximab and cisplatin in patients with recurrent or late-stage squamous carcinoma of the head and neck.³⁰ In this study, 67% of patients demonstrated a major response with the addition of cetuximab.³⁰ This drug also showed efficacy in improving the response rates in patients with head and neck cancer when combined with cisplatin, 5-FU, and radiation.³² As such, in 2006, cetuximab was approved by the FDA for the treatment of squamous cell carcinoma of the head and neck in combination with radiation therapy or as a single agent in cases refractory to platinum-based regimens.⁴⁴ Thus, cetuximab has demonstrated efficacy for the treatment of several cancers that in the past have been difficult to treat, and the recognition of optimal applications is growing. Although still under active investigation for more general use, this agent holds promise for treating a variety of cancers.

Another human monoclonal antibody that targets EGFR, panitumumab, has a different mechanism of action. Panitumumab functions by binding to the site of epidermal growth factor and tumor necrosis factor- α (TNF- α) binding on the EGFR.⁴⁵ The antibody is then internalized and downregulates EGFR production, induces apoptosis, and inhibits tumor growth and cell cycle progression.⁴⁵ Panitumumab has

been approved by the FDA for the treatment of EGFR-expressing metastatic colorectal cancer refractory to fluoropyrimidine-, irinotecan-, or oxaliplatin-based therapies.⁴⁶ Similar to cetuximab, however, several studies have identified *K-ras* mutation as a predictive marker for panitumumab response and thus recommend that *K-ras* status be identified prior to the initiation of treatment.⁴³ Recent work also has identified additional markers that have the potential to predict tumor response to monoclonal antibodies, such as cetuximab and panitumumab. For example, *BRAF*, *N-ras*, and *PIK3CA* have been suggested as potential biomarkers for response to anti-EGFR therapy and hold promise for further personalizing cancer treatment.^{47,48}

Finally, other similar agents, such as pertuzumab, an antibody that prevents dimerization of HER-2 receptors, are being developed and tested.⁴⁹ In vitro, pertuzumab demonstrated synergy with trastuzumab in inhibiting breast cancer cell growth. A phase I trial demonstrated that this drug was well tolerated and produced promising preliminary clinical results.^{49,50}

Small Molecule TKIs

Gefitinib is a small molecule inhibitor that targets the epidermal growth factor receptor 1 (EGFR1/HER-1) by inhibiting autophosphorylation.²⁷ This small molecule binds the intracellular TK domain of the receptor.^{51,52} Gefitinib was originally approved for the treatment of non-small cell lung cancer in 2003. However, in 2005, its use was limited only to patients who had previously benefited from the drug after two clinical trials demonstrated no advantage in patients with non-small cell lung tumors that overexpressed EGFR.⁵³ As clinical testing has continued, the results with gefitinib treatment have been mixed. Recent data from the North-East Japan Study Group indicated that first-line gefitinib prolonged progression-free survival in patients with metastatic non-small cell lung cancer with EGFR mutation(s) compared with carboplatin and paclitaxel.⁵⁴ In contrast, other studies have failed to show any improvement in survival.^{55,56} Interestingly, gefitinib appears to reverse drug resistance in breast cancer cells that overexpress Pgp, a multidrug resistance protein, suggesting that this may also be a therapeutic target for this agent.⁵⁷

Erlotinib is another small molecule inhibitor of EGFR autophosphorylation that binds the kinase domain of the receptor and inhibits cell proliferation and cell cycle progression. In preclinical trials, erlotinib effectively inhibited activation of EGFR in colorectal cancer cells, inhibited in vivo growth of squamous cell head and neck cancer cells that overexpress EGFR, and inhibited in vivo growth of non-small cell lung cancer cells.^{58–60} In a large randomized, placebo-controlled, double-blind trial studying patients with advanced non-small cell lung cancer (stage IIIB or IV), erlotinib therapy prolonged progression-free and overall survival and was subsequently approved as second-line therapy for treating non-small cell lung cancer in 2004.^{61–64} Later, erlotinib was approved in combination with gemcitabine for treating pancreatic cancer (2005) and as maintenance therapy for non-small cell lung cancer (2010).⁶⁴

Multitargeted Inhibitors

Despite the demonstrated efficacy of monoclonal antibodies and small molecule inhibitors of TKIs, the development

of resistance has been a concern and, as such, has led to the development of second-generation TKIs that are capable of inhibiting multiple TKs. These molecules are designed to inhibit not only EGFR/HER-2 activation, for example, but also downstream cell signaling molecules such as the src family of kinases and proteins such as c-kit, HER-2, and PDGFR.⁶⁵

Lapatinib is an EGFR and HER-2 inhibitor that has been extensively studied in the treatment of breast cancer. The unique feature of this inhibitor is the extended binding time to EGFR that prolongs its inhibitory effect. As a single agent, only modest clinical benefit was appreciated in phase II trials. However, lapatinib appears to be effective when used in combination with other agents. For example, in patients with metastatic breast cancer who overexpress HER-2, treatment with lapatinib plus capecitabine markedly improved progression-free survival. Also, patients receiving the combination regimen showed 51% reduction in risk of disease progression, decreased incidence of central nervous system (CNS) metastases, and decreased volume of existing CNS metastases.²⁷ In 2007, lapatinib in combination with capecitabine was approved by the FDA for use in advanced breast cancers that overexpress HER-2. In addition, in 2010, the FDA approved the combination of lapatinib and letrozole in postmenopausal women with advanced breast cancers who overexpress HER-2 and are hormone receptor positive. The combination regimen significantly improved progression-free survival.⁶⁶

Another of the second-generation, multitargeted TKIs, dasatinib, has demonstrated increased inhibitory activity against Bcr-Abl compared with imatinib in vitro and is currently approved for the treatment of CML in patients who have developed resistance to imatinib or are otherwise intolerant of the drug.^{8,65} In the SRC/ABL Tyrosine kinase inhibition Activity Research Trials of dasatinib (START-C) trial, 53% of patients who received dasatinib achieved a complete cytogenetic response and 62% achieved a major cytogenetic response after 24 months.^{8,67} Although this investigation involved the initiation of dasatinib treatment after failure of imatinib, there is speculation and early evidence that it may be effective as a first-line agent. Initial studies have suggested that the rate of remission at 24 months was superior with initial treatment of dasatinib when compared with initial treatment with imatinib.^{8,68}

Additional multitargeted agents are also under development. For example, neratinib inhibits both EGFR (ErbB1), HER-2 (ErbB2), and HER-4 (ErbB4), and in a phase I study for use against solid tumors, the agent was well tolerated and showed promising clinical activity.⁶⁹ A phase II trial of its use against advanced breast cancer supported early findings, and further studies are under way for the treatment of breast cancer and other solid tumors.^{10,70}

Another group of TKIs that target multiple receptors is difficult to classify because these agents affect a variety of kinases and downstream signaling cascades. For example, some of these molecules inhibit angiogenesis by blocking the vascular endothelial growth factor receptor (VEGFR) while also inhibiting TKs such as c-kit and HER-2. One such inhibitor is sunitinib, a molecule that inhibits c-kit, PDGFR- α , CSF-1 receptor, and VEGFR-1, -2, and -3.²⁷ The FDA approved its use in advanced renal cell carcinoma after it demonstrated efficacy by improving progression-free survival

and overall survival compared with interferon alfa.^{71,72} Sunitinib has also been used successfully to treat GISTs that have developed resistance to imatinib and is FDA approved for use in that setting.^{71,73,74}

Other clinical trials test sunitinib's efficacy in a variety of settings, and a phase II study using sunitinib for treating thyroid cancer that was resistant to radioactive iodine showed that 3% of patients had a complete response, 29% showed a partial response, and 46% maintained stable disease.⁷⁵ In addition, for metastatic breast cancer patients who failed treatment with anthracyclines and taxanes, sunitinib treatment helped some (5%) achieve stable disease.⁷⁶ Despite these promising results, toxicity has emerged as a concern with this agent. For example, in the study treating metastatic breast cancer, dose modification was necessary in 56% of patients as a result of adverse effects.⁷⁶ Similarly, in a study combining sunitinib with cyclophosphamide and methotrexate, of the 15 patients studied, three developed neutropenia and five developed mucositis.²⁷ In another phase I dose-escalation study combining sunitinib and capecitabine in patients with solid tumors, five grade 3 adverse effects emerged: abdominal pain, mucosal inflammation, fatigue, neutropenia, and hand-foot syndrome.⁷⁷ Similar side effects have been reported in other clinical trials, and one trial was terminated early because of the high incidence of neutropenia, febrile neutropenia, and fatigue.²⁷ Interestingly, in one study of efficacy against hepatocellular carcinoma, the neutropenia and skin toxicities seemed to correlate with response to therapy, overall survival, and time to tumor progression, suggesting that those toxicities may be a marker for tumor response.⁷⁸

Axitinib is another inhibitor of several RTKs, including all VEGFRs (1, 2, and 3), PDGFR- β , and c-kit.²⁷ This agent has shown promise in phase I studies and was initially thought to have few severe side effects (hypertension was most common). Phase II studies have suggested a benefit to adding axitinib to docetaxel for patients with metastatic breast cancer and in combination with gemcitabine for treating metastatic pancreatic cancer.^{27,79} In the phase II trials, however, toxicity appeared to be greater than suggested in the phase I trials (febrile neutropenia, fatigue, stomatitis, diarrhea, hypertension), and a phase III trial combining the agent with gemcitabine was terminated early because of a lack of improved survival.^{27,80} Clinical trials continue to investigate the use of axitinib for the treatment of a variety of solid tumors, including, but not limited to, renal cell carcinoma, hepatocellular carcinoma, colorectal cancer, lung cancer, and melanoma.¹⁰

Finally, vandetanib is a molecule that inhibits EGFR, the kinase domain of VEGFR2, and ret autophosphorylation that is currently in the early stages of clinical investigation.^{27,81–85} Phase I data suggest that although this agent is well tolerated, it provided no clinical benefit for patients with multiple myeloma.⁸¹ Early clinical trials for use against refractory non-small cell lung cancer, however, were more promising, prompting the initiation of phase III investigations for its use in that disease.^{83,85} The Ziprasidone Observational Study of Cardiac Outcomes (ZODIAC) trial examined the effect of vandetanib with docetaxel on previously treated non-small cell lung cancer; compared with patients who received docetaxel with placebo, patients who received vandetanib had significantly longer progression-free survival and an improved

overall response rate.⁸⁶ Early clinical trials in glioblastoma and medullary thyroid cancer also have shown promising results.^{87,88} At present, the indications for the use of these agents, both alone and in combination with other drugs, are evolving and await the results of clinical trials.

TKIs are the prototype for targeted therapeutics. These agents have been widely studied, and new and increasingly effective molecules are under development. Interestingly, one consistent theme with TKIs is the ability of biomarkers such as *K-ras* mutation and EGFR overexpression to predict response. This improved understanding of the molecular mechanisms underlying carcinogenesis and tumor response to therapy increasingly is leading to a more individualized approach to cancer treatment.

Angiogenesis Inhibitors

BIOCHEMICAL RATIONALE

Angiogenesis is one of the earliest events in tumor growth.⁸⁹ Hypoxic conditions provoke tumor microvascular formation by not only inciting proangiogenic signals but also inhibiting antiangiogenic signals.^{90–92} The proangiogenic factors released include, but are not limited to, vascular endothelial growth factors (VEGFA, -B, -C, -D, and -E), basic fibroblast growth factor (bFGF), interleukin-8, placental growth factors (PLGF-1 and -2), neurophilins (NRP1 and NRP2), transforming growth factors (TGFs), fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF).^{3,89,93} The effects of these proangiogenic proteins can be classified based on the mechanism by which they stimulate microvascular formation.⁸⁹ For example, some stimulate new growth of vasculature from preexisting blood vessels, whereas others induce the formation of de novo vascular channels.⁹⁴ VEGFR stimulation activates intracellular phospholipase C γ (PLC- γ), protein kinase C (PKC) and the MAPK pathway, PI $_3$ kinase, Akt/PKB (protein kinase B), nuclear factor κ B (NF- κ B), and endothelial nitric oxide synthases and inhibits proapoptotic proteins, thereby inducing endothelial cell survival, proliferation, and migration and increasing vasodilation, vascular remodeling, and vessel permeability.⁹⁵ In addition, hypoxia-inducible factors (HIFs) are transcription factors that are activated under hypoxic conditions and serve as a major stimulus for angiogenesis.⁸⁹

Folkman's hypothesis suggests that approximately 2 mm³ is the critical tumor size at which further growth and survival depend on an autonomous vascular network.⁹⁶ The resulting neovasculature is tortuous and irregular, and although not efficient enough to satisfy the oxygen needs of the growing tumor, these networks are able to promote growth and metastasis.⁸⁹ The most important cell involved in this process is the vascular endothelial cell, and its growth is primarily regulated by VEGF activation of the VEGFR. In normal tissues, VEGFR2 appears to be the major inducer of angiogenesis, whereas the relatively weak signal cascade of VEGFR1 may actually decrease angiogenesis. VEGFR3 is involved in embryologic and postnatal angiogenesis and lymphangiogenesis. In cancer, VEGFR1 and -2 appear to be the receptors most involved in tumor angiogenesis.³ Both VEGF and VEGFRs have emerged as logical targets for drugs seeking to inhibit angiogenesis.^{42,89}

ANGIOGENESIS INHIBITORS

Bevacizumab is the prototypical angiogenesis inhibitor. This anti-VEGFA antibody reduces the amount of effective circulating VEGFA and thereby prevents VEGFR activation.⁴² Bevacizumab has shown efficacy in suppressing endothelial cell adhesion and proliferation in vitro and suppressing peritoneal dissemination of gastric cancer in a murine model.^{97,98} Clinical efficacy was first demonstrated in colorectal cancer. In stage IV disease, bevacizumab in combination with irinotecan, 5-FU, and folinic acid (leucovorin) (FOLFIRI) induced higher response rates and prolonged progression-free and overall survival compared with traditional chemotherapy.⁹⁹ In 2004, bevacizumab was approved by the FDA as a first-line treatment for metastatic colorectal cancer and in 2006 as second-line treatment in combination with oxaliplatin, folinic acid, and 5-FU (FOLFOX4).^{100,101} The efficacy of bevacizumab has subsequently been tested in other tumor types, including pancreatic and hepatocellular carcinoma, renal cell carcinoma, neuroendocrine tumors, non-small cell lung cancer, and breast, brain, and ovarian cancers.¹⁰

Despite early enthusiasm about bevacizumab, additional experience has met with mixed results. The Bevacizumab Regimens' Investigation of Treatment Effects (BRiTE) study, an observational cohort study of 1,953 patients with metastatic colorectal cancer from 248 United States sites between 2004 and 2005, examined the efficacy of bevacizumab combined with chemotherapy as first-line treatment for metastatic colorectal cancer. At 20 months, progression-free survival was observed in 22% of patients who had received bevacizumab, whereas disease progression was seen in 79% of the patients. In addition, 66% of patients died during the study period, and 12% either withdrew from the study or were lost to follow-up.¹⁰² Similarly, in a phase III study by Stathopoulos and colleagues in 2010, median overall survival did not differ between groups that received bevacizumab with chemotherapy (irinotecan, 5-FU, leucovorin) and groups that received chemotherapy alone as the initial treatment for metastatic colorectal cancer.¹⁰³ Moreover, in a phase II study of bevacizumab with erlotinib for treating recurrent malignant glioma, progression-free survival was not significantly improved in patients who received bevacizumab.¹⁰⁴ Other early studies, however, have suggested efficacy in the treatment of other types of cancer. In non-small cell lung cancer, the effects on overall survival were inconsistent, but the drug appeared to slow the progression of the disease.¹⁰⁵ In vitro data suggest efficacy in combination with docetaxel for treatment of breast and prostate cancers.¹⁰⁶ In combination therapy with paclitaxel for metastatic breast cancer, bevacizumab improved response rates compared with paclitaxel alone.¹⁰⁷

To date, the FDA has approved bevacizumab in combination with carboplatin and paclitaxel for the treatment of non-small cell lung cancer and in combination with interferon for the treatment of metastatic renal cell carcinoma.^{101,108,109} It has also been approved for use as a second-line single agent for the treatment of glioblastoma.¹⁰¹ In 2008, bevacizumab was approved as first-line treatment in combination with paclitaxel for metastatic HER-2-negative breast cancer.¹⁰¹ However, the results of more recent analyses of several clinical trials have failed to show any survival advantage in breast

cancer patients who receive bevacizumab compared with chemotherapy alone. As a result, the Oncologic Drugs Advisory Committee of the FDA has recommended withdrawing the approval of bevacizumab as first-line treatment for metastatic breast cancer.¹¹⁰ The FDA is currently reviewing the data on this drug, and the decision regarding possible revocation of approval is pending.¹¹¹

Toxicity, although not prohibitive, is common, and the most common adverse effects are rash, hepatotoxicity (elevated liver function tests), proteinuria, diarrhea, myelosuppression, fatigue, infection, pain, nausea/vomiting, and hypokalemia.^{104,105,107,112} In addition, the BRiTE study found several rare, but more severe, side effects. New onset or worsening hypertension was seen in 22% of patients, and hypertension was implicated in eight serious adverse events. Additional less common but serious adverse events included postoperative wound healing complications (4%), grade 3 to 4 bleeding (2.2%), arterial thromboembolic events (2%), and gastrointestinal perforation (2%). The majority of bleeding events were gastrointestinal. Significant postoperative wound healing complications occurred following major surgery and in patients in whom surgery was undertaken within 2 weeks of the last bevacizumab dose.¹⁰² This observation has led most surgeons to try to avoid operating on patients within 6 to 8 weeks of bevacizumab therapy. Moreover, the FDA has issued a drug warning and safety labeling update concerning these adverse effects.¹⁰¹

Aflibercept (VEGF Trap) is a molecule in which the ligand-binding domains of the VEGFR1 and VEGFR2 proteins are fused with human IgG1, forming a decoy receptor that binds all VEGFs and placental growth factor.²⁷ Preclinical studies have suggested that this agent is well tolerated but have failed to show significant clinical activity. Definitive recommendations about the use of aflibercept await the results of ongoing trials.²⁷

Angiogenesis inhibitors have demonstrated efficacy in a variety of disease sites; however, they also have limitations. Of particular concern to surgeons are the risk of increased bleeding and inhibition of wound healing. Nevertheless, antiangiogenic compounds have proven to be useful in well-selected patients.

Cell Cycle Inhibitors

BIOCHEMICAL RATIONALE

Regulation of the cell cycle involves a highly complex sequence of events orchestrated by cyclins and cyclin-dependent kinases (CdKs) [see Figure 3]. The interaction of these molecules is regulated by several naturally occurring cyclin-dependent kinase inhibitors (CdKIs) that prevent binding of CdKs to cyclins. Two families of CdKIs have been identified: the INK4/ARF family and the Cip/Kip family. The INK4/ARF family includes p15, p16, p18, and p19, and the Cip/Kip family includes p21, p27, and p57.^{113,114} A cell will exit the quiescent phase, G₀, and enter G₁ following the production of cyclin D, which is the result of activation of the Ras/Raf/MAPK signal cascade by mitogens. Progression through the cell cycle is permitted to occur when the CdKIs do not prevent CdK-cyclin interactions. For example, cyclin E-CdK2 complex formation promotes cell entry into

Figure 3 Progression through each phase of the cell cycle is regulated by cyclin-cyclin-dependent kinase interactions. Adapted from www.sysmex-lifescience.com (accessed October 2010).

S phase, and cyclin B–Cdk1 allows mitosis to occur^{115,116} [see Figure 3]. Overall, nine CdKs have been described, and these molecules interact with 20 possible cyclins (A to T).¹¹⁵ Given that cyclins and CdKs play major roles in controlling progression through the cell cycle, they are logically attractive targets for treating cancer. In addition, there is evidence that CdK or cyclin production is disrupted in several malignancies, including melanoma and lung, breast, and colorectal cancers.^{115,117,118} Several cell cycle inhibitors are currently under investigation, but clinical results have been mixed, and it has been suggested that these agents may have more utility as chemosensitizers for other agents.¹¹⁵

CELL CYCLE INHIBITORS

Currently, CdKis include flavopiridol, roscovitine, E7070, AZD5438, SNS-032 (BMS-387032), bryostatin-1, PD 0332991, and SCH 727965. Flavopiridol acts on the G₁ and S phases of the cell cycle via inhibition of CdKs 2, 4, 6, and 9 and has demonstrated early success in vitro by inducing arrest of cellular growth and inducing apoptosis in chronic lymphocytic leukemia (CLL) and colorectal cancer cells.^{119,120} Currently, flavopiridol is useful for treating recurrent CLL, where it has been shown to induce a clinical response in patients with high-risk genomic features.¹²¹ In addition, when given with cytosine arabinoside and mitoxantrone, flavopiridol induced complete remission in 67% of patients with AML who had poor-risk features (older age, unfavorable genetic mutations, or secondary AML).¹²² Phase I trials indicate drug tolerability, and phase II trials continue to test this drug's efficacy in a variety of cancers.¹²³

Roscovitine inhibits cyclin E–Cdk2, cyclin B–Cdk1, cyclin H–Cdk7, and cyclin T1–Cdk9 and prevents progression through the S, G₂, and M phases of the cell cycle.¹¹⁵ In vitro studies also indicate that this drug induces apoptosis by activating p53, suppressing NF-κB, and downregulating Mcl-1 (an antiapoptosis protein) in multiple myeloma cells.^{124–126} It also inhibits mitosis by decreasing production of promoters of cell division, such as Aurora-A/B, CDC25C, pololike kinase,

and WEEL.¹²⁷ Preclinical studies have demonstrated the efficacy of this agent in a variety of cancer cell lines. A phase II clinical trial of roscovitine for treating resistant non-small cell lung cancer has recently been completed, and phase I investigation of its clinical safety in treating any solid tumors resistant to standard treatment is under way.¹⁰

E7070 is a synthetic sulfonamide that inhibits Cdk2 and cyclin E, effectively inhibiting progression through G₁ and S phases.¹²⁸ In vitro, this agent blocked cell cycle progression in non-small cell lung cancer cells, and in vivo, it not only inhibited tumor growth but also induced regression in models of colon cancer and non-small cell lung cancer.^{129,130} Four phase I clinical trials are currently under way evaluating the use of this agent in solid tumors and melanoma. However, the results of phase II trials in other disease sites have been somewhat disappointing. For example, E7070 as a single agent did not show significant response in non-small cell lung cancer.¹³¹ In 2005, Smyth and colleagues reported similar results in metastatic melanoma, with the best response being stable disease in 17% of patients, whereas 58% experienced disease progression.¹³² A phase II study in squamous cell head and neck cancer was terminated because of the 15 patients who were treated, none achieved 4 months of progression-free survival.¹³³ In addition, toxicity was concerning in these trials, prompting some patients to withdraw. Most common problems consisted of gastrointestinal upset (nausea, vomiting, constipation, or diarrhea) and pain at the injection site.¹³¹ However, more severe side effects, such as anemia, thrombocytopenia, bleeding, and one reported death attributable to pulmonary embolus, have also been attributed to E7070 treatment.¹³² Since the conclusion of those trials, pharmacokinetic studies have been initiated in an effort to identify the optimal dose of E7070 in combination with other agents in an attempt to minimize toxicity.^{134,135}

A number of additional cell cycle inhibitors are currently undergoing early clinical evaluation for the treatment of a variety of malignancies [see Table 2]. One such agent is SNS-032, an aminothiazide-based inhibitor that halts cell cycle progression by way of Cdk2 and -7 inhibition, and transcription via Cdk7 and -9 inhibition.^{136,137} Interestingly, the antitumor efficacy of SNS-032 may also result from inhibition of VEGF expression, hindering angiogenesis.¹³⁸ Phase I investigations of oral bioavailability in patients with metastatic solid tumors and lymphomas, as well as previously treated CLL and multiple myeloma patients, indicate that oral administration is feasible, and although neutropenia and thrombocytopenia were the most common side effects, the agent was largely well tolerated.^{137,139}

Bryostatin-1 is a macrocyclic lactone derived from *Bugula neritina*.¹⁴⁰ This natural antineoplastic agent affects protein kinase C levels, inhibits Cdk2, and induces p21.^{115,141} Although promising in preclinical investigations, the results of phase II studies have shown inconsistent efficacy as a single agent or in combination with other agents. Some trials, however, did report disease improvement with bryostatin-1 treatment. Most recently, Barr and colleagues demonstrated that combination bryostatin-1 and vincristine induced an overall response rate of 31% with complete remission of disease in two patients with non-Hodgkin lymphoma.¹⁴² Clinical trials continue to test this agent under myriad conditions.¹⁰

Table 2 Cell Cycle Inhibitors

<i>Cell Cycle Inhibitor</i>	<i>Mechanism of Action</i>	<i>Effects</i>	<i>Clinical Trials*</i>
Flavopiridol	Inhibits Cdk 2, 4, 6, 9	G ₁ /S arrest	Phase I/II (hematologic and several solid tumors)
Roscovitine	Inhibits cyclin E/Cdk2, cyclin B/Cdk1, cyclin H/Cdk7, cyclin T1/Cdk9; p53 activation, nuclear factor κB, decreases Mcl-1	S/G ₂ /M arrest	Phase I/II (solid tumors)
E7070	Inhibits Cdk2, cyclin E	G ₁ /S progression	Phase I/II (several solid tumors, melanoma)
SNS-032	Inhibits Cdk 2, 7, 9, VEGF	Inhibits progression and transcription, angiogenesis	Phase I (advanced B cell lymphomas, several solid tumors)
Bryostatin-1	Affects protein kinase C, Cdk2; induces p21	Cell cycle modulation	Phase I/II (combination therapy for hematologic and several solid tumors)
AZD5438	Inhibits Cdk1, 2, 9	Affects all phases of cell cycle	Trials terminated due to safety concerns

*Adapted from www.clinicaltrials.gov.¹⁰

Cdk = cyclin-dependent kinase; VEGF = vascular endothelial growth factor.

Finally, AZD5438 is one cell cycle inhibitor that exemplifies the difficulty in translating laboratory outcomes to clinical practicality. This agent worked through all phases of the cell cycle by inhibiting Cdk1, -2, and -9.^{115,143} Preclinical data were promising, but the clinical trials yielded less favorable outcomes. The most recent phase I trial published, studying patient tolerance of AZD5438 for the treatment of recurrent solid malignancies, indicated that weekly dosing was more appropriate than continuous. However, safety concerns prompted manufacturer discontinuation of the agent and thus resulted in early termination of clinical trials.¹⁴⁴

Cell cycle inhibitors are in the early stages of evaluation, and some have shown promising initial results in combination with other chemotherapies. However, although tumor cells demonstrate accelerated cell turnover and, as such, should be most sensitive to these agents, the nonspecific targeting of the cell cycle can injure normal tissues. Thus, as is the case with angiogenesis inhibitors, toxicity remains a major concern and has limited the clinical applicability of some of these drugs.

Inducers of Apoptosis

BIOCHEMICAL RATIONALE

Apoptosis is the natural process of programmed cell death, and two pathways are involved in this process. The extrinsic pathway is mediated by death receptors such as Fas, TNF, and TRAIL, among others. The intrinsic pathway is mitochondria and apoptosome mediated and can be activated by radiation and chemotherapy. It includes downstream signaling mediated by bcl-2 and the bcl-2 family of antiapoptotic or proapoptotic proteins (e.g., Bid, Bax, Bak), as well as caspases and cytochrome-c. These pathways are not mutually exclusive; for example, caspases are known to participate in both intrinsic and extrinsic pathways. Naturally occurring apoptosis proteins interact with the caspases to either inhibit or induce the innate process of programmed cell death.^{145,146} Although these molecules balance the proapoptotic/antiapoptotic equilibrium, changes in any number of elements in the signal cascade may disrupt normal apoptosis.

For example, a mutation resulting in the loss of antiapoptotic p53 functions can lead to genomic instability and decreased apoptosis. Cancer therapies that target the inappropriate loss of control over apoptosis have been developed to induce the intrinsic and extrinsic pathways either independently or together. Recent work has focused on inhibition of pathways involving the TRAIL receptor, bcl receptors, and inhibitors of apoptosis proteins (AIPs).¹⁴⁷

APOPTOSIS-INDUCING AGENTS

Apoptosis inducers can be classified based on their mechanism of action. Bortezomib, suberoylanilide hydroxamic acid (SAHA), TLK286, ONYX015, FTI-R115777, and 17AAG target protein kinases, proteasomes, and transcriptional factors. Mapatumumab and lexatumumab target the proapoptotic proteins TRAILR1 and TRAILR2.

Bortezomib is a boronic acid dipeptide and was the first proapoptotic agent used in cancer treatment. Bortezomib promotes apoptosis by inhibiting the 26S proteasome.¹⁴⁸ This proteasome degrades many cellular proteins, including those involved in the cell cycle, transcription, and tumor suppression. Early work suggested that 26S proteasome inhibition promoted apoptosis in multiple myeloma cells and that this molecule stabilized tumor suppressor and cell cycle proteins (p53, p21, and p27).¹⁴⁸ The Assessment of Proteasome Inhibition for Extending Remissions (APEX) trial suggested superior efficacy of bortezomib over dexamethasone for refractory multiple myeloma.¹⁴⁹ Clinical trials also suggest that this agent may effectively augment the antitumor activities of established chemotherapy regimens. For example, the Velcade as Initial Standard Therapy in Multiple Myeloma (VISTA) study was a phase III clinical evaluation of bortezomib in combination with melphalan and prednisone as first-line therapy for multiple myeloma. The addition of bortezomib to the standard melphalan-prednisone regimen slowed time to disease progression, increased the incidence of partial and complete response, and prolonged the duration of response.¹⁵⁰ Further follow-up showed that patients treated with a combination of bortezomib, melphalan, and prednisone had better overall survival at 3 years (69% versus 54%),

and 35% reduced risk of death at 26.7 months when compared with patients who received only melphalan and prednisone.¹⁵¹ The FDA approved bortezomib as a second-line therapy for the treatment of mantle cell lymphoma in 2006 and as first-line therapy for multiple myeloma in 2008.¹⁵²

Several clinical trials have studied the efficacy of bortezomib against solid tumors, such as hepatocellular carcinoma and metastatic rectal cancer.^{153–155} Bortezomib has also been proposed as a radiosensitizer in combination with 5-FU for neoadjuvant treatment of locally advanced (stages II and III) rectal cancer. However, in a small study, only one of nine patients treated had a complete pathologic response, arguably equivalent to 5-FU-based strategies alone.¹⁵⁴ At present, there are no indications for use of this agent in solid tumors, despite its efficacy in hematologic malignancies.¹⁵⁶

SAHA inhibits histone deacetylase, thereby suppressing the expression of genes that can promote tumorigenesis.¹⁵⁷ In vitro and in vivo studies indicated that histone deacetylase inhibitors such as SAHA downregulate TNF- α receptor-1 expression and activation of NF- κ B.¹⁵⁸ Several clinical trials have been completed, and in 2006, the agent was approved by the FDA as a third-line treatment option for cutaneous T cell lymphoma.¹⁵⁹ The trials that led to approval demonstrated that patients who had previously failed treatment benefited from treatment with SAHA. Side effects were tolerable, and the most common adverse effects were fatigue (52%), diarrhea (52%), and nausea (40%). More serious effects (pulmonary embolism, deep vein thrombosis, myocardial infarction) occurred in fewer than 10% of patients.¹⁵⁹ Additional clinical investigations are under way, including a phase III trial of SAHA use against advanced mesothelioma.¹⁶⁰

Several other agents designed to induce apoptosis are under investigation [see Table 3]. TLK286, a modified glutathione analogue, is metabolized by glutathione S-transferase (GST) in the tumor cell cytosol, yielding a molecule that is toxic to the cell. Because GST is overexpressed in many resistant

tumor cells, TLK286 may be an ideal therapeutic option in these refractory tumors.^{161,162} Preliminary data suggest that TLK286 has little efficacy as a single agent, but combination with other agents may be useful.^{163–167} A phase III study comparing TLK286 with doxorubicin or topotecan as a third-line treatment for refractory ovarian, fallopian, or primary peritoneal cancer is currently under way.¹⁶⁸

The adenovirus ONYX015 is an attenuated adenovirus that has also shown antitumor activity, although the mechanism of action remains poorly understood. It was initially thought that the virus selectively invades and replicates in *p53* mutated cells and binds to and inactivates the *p53* gene but has no effect on normal cells.^{169,170} However, other studies have suggested that its efficacy results from more complex interactions and not just mutated *p53*.^{171,172} In 2004, the agent was approved in China for use against squamous cell head and neck cancer, and in the United States, it has shown promise in phase I and II trials as combination therapy for patients with solid tumors such as advanced sarcoma and recurrent head and neck cancer.^{173–175}

Another agent that induces apoptosis is FTI R115777, a methylquinolone farnesyl transferase inhibitor (FTI). Initially thought to inhibit cell growth and induce apoptosis solely by blocking farnesylation of Ras, it now appears that FTI R115777 also induces cell death by disrupting the mitochondrial membrane and inducing caspase-9 activation.¹⁷⁶ Early clinical trials have yielded mixed results. The Children's Oncology Group, however, recently reported that although the pharmacokinetics were more variable in the pediatric population, the agent is well tolerated for the treatment of pediatric hematologic malignancies, and further investigation in solid tumors and neurofibromatosis type 1-related plexiform tumors is warranted.^{177,178}

7AAG is an inhibitor of heat shock protein HSP90, a molecule that is frequently overexpressed in tumor cells.¹⁷⁹ This agent has been thoroughly studied in vitro and in vivo

Table 3 Inducers of Apoptosis

<i>Inducer of Apoptosis</i>	<i>Mechanism of Action</i>	<i>Effects</i>	<i>Clinical Trials*</i>
Bortezomib	Inhibits 26S proteasome	Decreased degradation of cell cycle and transcription proteins	FDA approved as first-line treatment of multiple myeloma and as second-line treatment of mantle cell lymphoma
Suberoylanilide hydroxamic acid (SAHA)	Inhibits histone deacetylase	Suppress tumorigenic gene expression	FDA approved as third-line treatment of cutaneous T cell lymphoma; phase III (advanced mesothelioma)
TLK286	Formation of a toxic metabolite	Induces apoptosis	Phase III (refractory gynecologic malignancies), combination therapy
ONYX015	Adenovirus; invades and replicates in <i>p53</i> mutated cells, inactivates <i>p53</i> gene	Lyses <i>p53</i> mutated tumor cells	Phase I/II (combination therapy for solid tumors)
FTI-R115777	Blocks farnesylation of Ras, disrupts mitochondrial membrane, induces caspase-9 activation	Inhibit cell growth and induce apoptosis	Phase III (colorectal cancer and AML; no significant improvement in progression-free survival or overall survival, respectively); phase I/II (pediatric leukemias, glioma)
17AAG	Inhibits HSP90	Inhibit cell motility and invasion	Phase I/II (multiple myeloma)
Mapatumumab	TRAILR1 agonist	Inhibit TRAIL ligand binding and apoptotic signal cascade	Phase I/II (several solid tumors)
Lexatumumab	TRAILR2 agonist		

*Adapted from www.clinicaltrials.gov.¹⁰
AML = acute myelogenous leukemia; FDA = Food and Drug Administration.

and affects a variety of cancer cell types by inducing apoptosis, decreasing growth, potentiating the effects of known chemotherapeutic drugs, and sensitizing tumors to radiotherapy.¹⁸⁰ Phase I and II trials suggest a tolerable safety profile and disease stability when administered as a single agent or in combination with bortezomib.^{181,182}

Another pathway targeted to induce apoptosis involves TRAILR1 and TRAILR2. TRAILR1 and TRAILR2 are two TRAIL receptors that are believed to be involved in apoptosis via FADD and caspase-8 or -10 recruitment and possibly by activation of other signaling pathways involving NF- κ B, MAPK, PI₃ kinase, and Akt. Initiated by TRAIL ligand binding, this process has been linked to tumorigenesis and is a promising target for anticancer therapy. Mapatumumab (HGS-ETR1) and lexatumumab (HGS-ETR2) are two monoclonal antibodies that agonistically bind the TRAILR1 and TRAILR2 receptors, respectively.¹⁴⁷ The role of mapatumumab and lexatumumab in combination with other agents has been supported by the observation of a synergistic effect with either antibody and cisplatin or bortezomib in non-small cell lung cancer cells and malignant mesothelioma cells or with radiotherapy in colorectal cancer cells.^{183–185} Clinical trials are under way for both mapatumumab and lexatumumab.¹⁰ Although well tolerated, the clinical response at the dose of mapatumumab administered was not significant.¹⁸⁶ Phase I trials also suggested that lexatumumab is safe and well tolerated and has promising clinical efficacy.^{187,188}

Thus, drugs designed to induce apoptosis are showing early promise for the treatment of a variety of cancers. Clinical trials suggest that the side effect profile does not limit use and that these drugs may be most effective as chemo- or radio sensitizers.

Focal Adhesion Kinase Inhibitors

BIOCHEMICAL RATIONALE

Focal adhesion kinase (FAK) is a non-RTK that was identified at adhesion sites between cells and the extracellular environment. The 125 kDa protein is encoded by a gene located on chromosome 8 and houses three domains, the amino-N-terminal domain, the central catalytic domain, and the carboxy-C-terminal domain. FAK activation relies on autophosphorylation of the Y397 site that is found in the N-terminal domain. This is also a binding and activation site for several signaling proteins, such as src, PI₃ kinase, and Grb-7. In addition, this region also binds extracellular matrix and signaling proteins involved in cell motility, invasion, and cytoskeletal changes, as well as EGFR, p53, and other molecules that are critical for carcinogenesis.¹⁸⁹ It is well known that p53 is mutated in many cancers; interestingly, p53 can inhibit FAK expression, and FAK can inhibit p53 expression. In breast cancer cells, p53 mutation is highly correlated with FAK overexpression.¹⁹⁰ Finally, FAK appears to play a key role in motility and migration, invasion, survival, angiogenesis, lymphangiogenesis, and proliferation¹⁸⁹ [see Figure 4].

FAK is upregulated in several types of cancer.¹⁸⁹ The potential role of FAK activation in cancer growth and progression has led to the development of several therapeutic agents targeting this molecule. Initial attempts were focused on downregulation of FAK expression. Subsequently, more

specific targeted therapeutic approaches have been developed using small molecules designed to inhibit FAK kinase activity and activation or to inhibit protein-protein interactions.

FAK INHIBITORS

Initial attempts at FAK inhibition focused on downregulating FAK expression. Early studies demonstrated that transfection of breast cancer cells with dominant negative C-terminal FAK-CD decreased adhesion, colonization, and in vivo tumor growth.¹⁹¹ Moreover, cells transfected with FAK-silenced RNA (FAKsiRNA) showed increased rounding, decreased growth, and decreased in vivo tumorigenesis.¹⁹¹ Combination FAK/src inhibition with adenoviral FAK-CD and the src inhibitor PP2 appeared to have a synergistic effect and functioned by increasing apoptosis.¹⁹² Thus, FAK inhibition via silencing FAK expression seems to decrease tumorigenesis in vitro and in vivo.

Another approach to FAK inhibition involved either activation of p53 or elimination of p53-deficient cells. This indirect approach was studied by introducing retroviruses that express p53 into rapidly dividing p53-deficient cells. A similar tactic was applied in the development of AD5CMV-p53, an adenoviral vector encoding p53 that was subsequently used to replenish p53 deficiency in tumor cells. This approach inhibited lung cancer cell growth in vitro and in vivo.¹⁹³ Clinically, phase I and II trials suggest that this agent is both safe and effective against esophageal squamous cell carcinoma.^{194,195} However, concerns about the safety of a viral vector and about the logistics of production and storage persist.¹⁹⁶

More recent efforts have focused on the development of small molecules to inhibit FAK activity. The first FAK inhibitor that was developed, TAE226, blocks the ATP-binding site and inhibits FAK phosphorylation at both Y397 and Y861, a site that is involved with VEGF signaling. This molecule showed promise in preclinical in vitro and in vivo trials and most recently was found to inhibit angiogenesis in models of human colon cancer.¹⁹⁷ TAE226 has not yet progressed to clinical evaluation.

In addition to TAE226, several other FAK inhibitors have been developed and are currently in phase I clinical trials. Like TAE226, PF-562,271 blocks the ATP-binding site of FAK and of Pyk2 (protein-rich tyrosine kinase 2), another nonreceptor tyrosine kinase known to bind and activate src.^{198,199} PF-562,271 inhibited in vivo breast cancer cell growth and metastasis in a murine model and decreased the in vivo growth of prostate cancer cells and in vitro growth of lung cancer cells.^{198,200–202} It also has exhibited synergy with sunitinib in the inhibition of hepatocellular tumor growth in vivo.²⁰³ Phase I clinical trials employing PF-562,271 for treating prostate, pancreatic, and head and neck cancers have recently been completed. Another inhibitor, PF-573,228, works similarly and has been found to inhibit breast cancer cell migration.²⁰⁰ Interestingly, this agent in combination with tamoxifen decreased proliferation in estrogen receptor-positive breast cancer cells.²⁰⁴ Other FAK inhibitors include PF-04554878, which is currently in phase I clinical trials for the treatment of advanced nonhematologic malignancies, and GSK2256098, which has completed phase I trials.¹⁰

PND-1186 is another FAK inhibitor with a different mechanism of action. PND-1186 likely inhibits ATP activity by substituting a pyridine ring for the pyrimidine ring found in

Figure 4 Focal adhesion kinase (FAK) plays a key role in a signaling cascade that can lead to some of the tumorigenic properties of cancer cells. FAK activation induces cell proliferation, motility, survival, invasion, and metastasis. Adapted from SABiosciences. Retrieved from www.sabiosciences.com (accessed October 2010). EGF = epidermal growth factor; EGFR = epidermal growth factor receptor; PLC- γ = phospholipase C γ .

other ATP-binding FAK inhibitors.^{205,206} Early studies show that this molecule increases breast cancer cell apoptosis, inhibits *in vivo* breast cancer cell growth and metastasis, and inhibits ascites and peritoneal seeding in models of ovarian cancer.^{205,207}

An obvious concern with any drug is the potential for toxicity. Theoretically, the more specific the drug, the less potential it has to produce untoward effects. Although inhibiting ATP binding prevents FAK activation, this effect is somewhat nonspecific and, as such, raises concern about potential toxicity. Specific inhibition of the Y397 phosphorylation site, without blocking ATP binding, may offer a more specific target for FAK inactivation. Recently, several small molecule inhibitors that directly target the Y397 autophosphorylation site have been developed.²⁰⁸ One such molecule, 1,2,4,5-benzenetetraamine tetrahydrochloride (Y15), binds specifically to the Y397 site, does not affect ATP binding or Pyk-2, and effectively inhibits FAK activation. *In vitro*, Y15 increased detachment and inhibited adhesion of breast cancer cells and tumorigenesis *in vivo*.²⁰⁸ Additional studies have demonstrated the efficacy of Y15 in inhibiting pancreatic and neuroblastoma tumor growth *in vivo*.^{209–211} In addition, when combined with gemcitabine, these two agents demonstrated synergy in inhibiting pancreatic cancer cell growth.²¹¹ This novel small molecule inhibitor of FAK activation, therefore, holds promise as a potential new therapeutic agent.

FAK inhibition has been a relatively new approach to targeted cancer therapy. This approach is unique, and early studies suggest that FAK inhibition, either alone or in combination with other agents, may provide novel anticancer regimens.

Conclusion

The oncologic arena is changing. As the understanding of the complexities of cell signaling, cell division, apoptosis, and angiogenesis, grows, so does the armamentarium of therapeutic agents against cancer. Some of these agents have been studied extensively and already are used clinically. Others that show promise are at the early stages of development. The objective of studying these molecules is to develop drugs that selectively target malignant cells while sparing normal cells. By doing so, not only can efficacy against cancer be improved, but toxicity can also be minimized. Thus, in addition to more traditional advances in surgical and medical treatment of cancer, targeted therapeutics increasingly will play a role in surgical oncology. This is an exciting area of development with a substantial collection of established regimens and promising new therapies on the horizon.

8 SOFT TISSUE SARCOMA

Aimee M. Crago, MD, PhD, and Samuel Singer, MD, FACS

The term *soft tissue sarcoma* (STS) defines cancers that develop from mesenchymal cells and their progenitors. STS is rare; the disease is diagnosed in approximately 10,000 individuals yearly in the United States.¹ This represents approximately 1% of adult malignancies and 15% of pediatric malignancies. We now recognize that, as rare as STS is, it actually represents an umbrella diagnosis encompassing over 50 different histologic subtypes of disease. Histologic subtype, in conjunction with tumor location, largely defines the biologic behavior of a given lesion and the associated clinical prognosis [see Figure 1]. Approximately half of all STSs occur in the extremities and 15% in the retroperitoneum [see Figure 2]. The most common histologic subtype in adults is liposarcoma (24% of extremity STS and 45% of retroperitoneal STS); other common subtypes are malignant fibrous histiocytoma (21% of extremity STS) and leiomyosarcoma (21% of retroperitoneal STS) [see Figure 3].

Unfortunately, the complexity created by diverse tumor characteristics means that treatment of STS is similarly complex. This chapter attempts to simplify the principles of STS therapy, defining an algorithm for patient evaluation and treatment while highlighting common indications for diverging from this strategy as dictated by disease subtype and location.

Etiology

Factors responsible for the development of sporadic STS are poorly understood, and few etiologic relationships have been definitively characterized. The disease is loosely associated with exposure to various herbicides and environmental toxins. The clearest of these connections are associations of vinyl chloride and thorium dioxide (Thorotrast) with hepatic angiosarcoma.² Patients who develop chronic lymphedema, often following surgical lymph node dissection, are also at risk for the development of angiosarcoma, a clinical scenario known as Stewart-Treves syndrome.³

Exposure to therapeutic and environmental radiation is a factor that clearly puts patients at risk for the development of STS. Radiation-induced sarcomas are defined as those occurring within the prior radiation field and having a pathologic confirmation of sarcoma that is histologically distinct from the primary cancer.⁴ In a population-based study of 295,712 patients with solid or hematologic tumors, those treated with radiation therapy had a twofold higher rate of sarcoma development compared with the general population. For patients who received radiation before age 55, the rate was fourfold higher than in the general population.⁵ The median interval between radiation administration and development of radiation-associated STS is 10 years. The most common

Figure 1 Disease-specific survival stratified by (a) histologic type and (b) tumor location. Data are derived from all cases of soft tissue survival evaluated, treated, and followed prospectively at Memorial Sloan-Kettering Cancer Center over a 25-year period. MFH/NOS = malignant fibrous histiocytoma/sarcoma not otherwise specified; MPNST = malignant peripheral nerve sheath tumor.

The authors and editors gratefully acknowledge the contributions of the previous authors, Eric Kimchi, MD, Herbert Zeh, MD, Yixing Jiang, MD, PhD, and Kevin Staveley-O'Carroll, MD, PhD, FACS, to the development and writing of this chapter.

Figure 2 Anatomic distribution of all cases of soft tissue sarcomas evaluated, treated, and followed prospectively at Memorial Sloan-Kettering Cancer Center over a 25-year period ($N = 7,850$).

subtypes of radiation-induced sarcoma are angiosarcoma (27%), high-grade malignant fibrous histiocytoma (26%), and leiomyosarcoma (12%). In retrospective and case-control studies, a sarcoma being radiation associated is an independent risk factor (by multivariate analysis) for disease-specific death.⁶

Although environmental causes for STS are incompletely understood, characteristic molecular changes have been

identified in many histologic subtypes of STS. These include chromosome amplifications, point mutations, and gene translocations. In many tumors, these genomic alterations can be used to identify the histologic subtype. For instance, well-differentiated and dedifferentiated liposarcoma cells have characteristic chromosome 12 amplifications that result in increased levels of MDM2 and CDK4 proteins, which can be stained by immunohistochemistry. In myxoid-round cell liposarcomas and synovial sarcomas, gene fusion products (FUS-CHOP and SSX-SYT, respectively) can be detected by polymerase chain reaction. With gastrointestinal stromal tumors (GISTs), genetic characterization (c-kit overexpression) has been used to identify the tumor; in addition, c-kit overexpression is targeted by imatinib in systemic treatment of the disease.

Germline mutations have also been associated with development of STS. Examples include Li-Fraumeni syndrome (*p53* mutation associated with STS and osteosarcoma), neurofibromatosis type 1 (von Recklinghausen disease; *NF1* mutation associated with progression of neurofibromas to malignant peripheral nerve sheath tumors), and Gardner syndrome (*APC* mutation associated with intra-abdominal desmoid tumors). These syndromes can be inherited. Childhood retinoblastoma, Werner syndrome, Gorlin syndrome, Carney triad, and tuberous sclerosis also carry increased risk of STS.

Tumor Staging and Patient Prognosis

T stage for STS is determined not only by tumor size (T1, 5 cm and below; T2, larger than 5 cm) but also whether the lesion is superficial (T1a or T2a) or deep (T1b or T2b) to the muscle fascia. Nodal disease (N1) is rare in STS patients;

Figure 3 Histopathologic distribution of (a) extremity soft tissue sarcoma ($n = 3,123$) and (b) retroperitoneal/intra-abdominal soft tissue sarcoma ($n = 1,241$). Data are based on all cases of soft tissue sarcoma evaluated, treated, and followed prospectively at Memorial Sloan-Kettering Cancer Center over a 25-year period. DFSP = dermatofibrosarcoma protuberans; DSRC = desmoplastic small round cell tumor; GIST = gastrointestinal stromal tumor; MFH/NOS/Undiff = malignant fibrous histiocytoma/sarcoma not otherwise specified/undifferentiated pleomorphic sarcoma; MPNST = malignant peripheral nerve sheath tumor; SFT/HPC = solitary fibrous tumor/hemangiopericytoma.

it does not confer a prognosis as poor as do distant metastases (M1).

The American Joint Committee on Cancer (AJCC) staging system for STS includes not only tumor size and the presence of nodal and metastatic disease, as in adenocarcinomas, but also tumor grade⁷; it is therefore termed TNGM staging. It should be noted, however, that the traditional AJCC grading system, which is based on differentiation (well, moderate, or poor), is not generally applicable to STS. Most sarcoma grading systems incorporate the histology-specific extent of differentiation, mitotic rate, and necrosis. The most widely accepted system, that of the French Federation of Cancer Centers Sarcoma Group (FNLCC), uses these three factors to classify sarcomas as low (G1), intermediate (G2), or high (G3) grade.

TNGM staging classifies STS into four broad stages.⁷ Stage I includes all localized, low-grade tumors. Stage II is localized intermediate-grade tumors or high-grade, localized tumors that are small and/or superficial. Stage III disease represents large (> 5 cm), high-grade tumors. Stage III disease also includes STS associated with nodal metastases independent of grade and size. Stage IV disease represents all disease associated with distant metastases.

Outcomes based on TNGM staging are shown in Figure 4. Although stage is a strong prognostic factor, there is a significant degree of variability among patients within each of the localized disease stages (stage I, II, or III) as relates to outcome after surgical resection of the primary tumor. One reason for this limitation may be that the AJCC system does not incorporate multiple prognostic factors important in STS. For example, tumor histology is of significant import; malignant peripheral nerve sheath tumors are associated with poorer disease-specific survival than are myxofibrosarcomas [see Figure 1a]. Given these facts, a prognostic nomogram has been developed from retrospective data collected from 2,163 patients treated at Memorial Sloan-Kettering Cancer Center [see Figure 5] and validated using a prospectively enrolled cohort of 929 patients treated at the University of California, Los Angeles.^{8,9} Tumor size, histologic subtype, and site of disease are all used to improve prediction of patient outcome. Prognostic accuracy is further enhanced by the fact that variables such as size and patient age can be considered continuous variables rather than being divided into a few categories, as they are in staging systems and risk category systems. A Web-based version of the STS nomogram is available for general reference (<http://www.mskcc.org/mskcc/html/6181.cfm>).

Evaluation and Treatment of Soft Tissue Sarcoma

Surgical excision of STS is the mainstay of our current treatment algorithm. A multidisciplinary approach to the disease is, however, essential, because of the complexity involved in histology-based treatment. The risks and benefits of radiation and chemotherapy as well as adjuvant and neoadjuvant approaches should be carefully weighed when determining the overall treatment plan for a patient with STS. Prevalence of histologic subtypes, treatment-related morbidities, and patterns of recurrence are very different for primary STS of the extremity or superficial trunk versus the abdomen or retroperitoneum. The sections below separately

describe extremity and truncal STS and abdominal and retroperitoneal STS.

EXTREMITY AND SUPERFICIAL TRUNCAL STS

Diagnosis and Evaluation

Patients with STS of the extremity and superficial trunk most commonly present with a palpable mass sometimes brought to their attention by a minor trauma in the region. After a careful history and physical examination, a magnetic resonance imaging (MRI) or computed tomographic (CT) scan is indicated for all but small (< 2 cm), superficial lesions, which can be evaluated by excisional biopsy. Cross-sectional imaging provides the size and location of the lesion and identifies involvement of adjacent structures. CT is readily available and less expensive, although MRI can provide better soft tissue definition in the extremity. Histologic subtype, which dictates appropriate treatment, is not, in most instances, well defined by CT or MRI. The exception to this rule is well-differentiated liposarcoma (atypical lipomatous tumors). On cross-sectional imaging, these lesions resemble normal fat in their signal intensity, appear encapsulated, and are associated with thick, internal septations.¹⁰ For tumors located deep to the investing fascia, imaging findings are almost pathognomonic for this subtype, and further workup is not warranted. These lesions should be completely excised with, when possible, a margin of normal muscle or fascial tissue to minimize the risk of local recurrence.

If the STS does not appear consistent with an atypical lipomatous mass, biopsy is indicated prior to defining a treatment plan. Performed improperly, the biopsy of an extremity mass can result in significant oncologic and cosmetic consequences when definitive excision is performed. For this reason, the principles of STS biopsy should be part of the core procedural knowledge for all general surgeons. Although incisional biopsy had been the standard method of diagnosis, core biopsy provides adequate tissue for evaluation in almost all cases and often leads to accurate diagnosis of histologic type and grade.¹¹ When performing a core biopsy for suspected STS, the surgeon or radiologist should first consider where the surgical incision will be placed. The biopsy site will be excised at the time of surgery and should, therefore, be placed directly adjacent to the planned surgical incision. If multiple cores are taken, they should be angled serially toward a different region of the tumor but always obtained through a single biopsy site.

In the event that core biopsy is insufficient for diagnosis or the lesion is too small to biopsy in this manner, incisional or excisional biopsy is performed. Again, careful planning of the biopsy is essential. The biopsy incision should always be oriented longitudinally along the limb. This is because the definitive surgery for excision of an STS will require resection of the biopsy incision with circumferential margins between 1 and 2 cm (depending on the histologic subtype of the STS). If a biopsy scar is oriented transversely, the diameter of the surgical specimen must increase dramatically to obtain adequate surgical margins. This often means that primary closure of the defect is impossible, and a skin graft or muscle flap is essential to cover the surgical bed.

All STS patients with high-grade disease should undergo a CT scan of the chest to evaluate for pulmonary metastases.

Figure 4 Disease-specific survival according to American Joint Committee on Cancer TNM stage based on all cases of soft tissue survival evaluated, treated, and followed prospectively at Memorial Sloan-Kettering Cancer Center over a 25-year period.

For those with low-grade disease, the risk of metastasis is minimal and chest x-ray is generally adequate and cost-effective. Many STSs are not fluorodeoxyglucose avid; therefore, positron emission tomography (PET) has poor sensitivity for use in the staging of these diseases.

After a pathologic diagnosis of STS has been obtained, the histologic subtype and grade have been identified, and the patient has been assessed for distal metastases, a multidisciplinary treatment plan can be defined. In most cases of localized disease, the primary treatment will be resection or, much less commonly, radiation (discussed below in the context of adjuvant radiation).

Surgical Planning

An algorithm for the treatment of extremity STS is shown in Figure 6.

Prior to 1981, the standard surgical approach to STS of the extremity was amputation. A randomized, controlled trial, coordinated at the National Cancer Institute, defined a role for limb-sparing surgery. The trial followed 43 patients with high-grade tumors treated with amputation or limb-sparing resection with adjuvant radiation. Five years after resection, patients undergoing limb-sparing surgery clearly had a higher

incidence of local recurrence, but their disease-free and overall survival rates were no different from those who underwent amputation. Patients experiencing a local recurrence were, in large part, salvaged with additional surgery.¹² Limb-sparing surgery is, therefore, currently considered the standard of care in STS surgery.

Resections should be carefully planned preoperatively to consider functional outcomes and risks of recurrent local disease and distal progression. Importantly, although many extremity lesions are associated with what appears on inspection to be a well-defined pseudocapsule, microscopic disease extends beyond this layer. Therefore, during limb-sparing procedures, a wide margin (1 to 2 cm) of normal tissue should be resected with the specimen to reduce the risk of local recurrence. When the tumor abuts a fascial plane of an adjacent muscle, this layer should be resected with the tumor. When the tumor is superficial, the underlying muscle fascia should always be resected.

When treating extremity STS, the surgeon should consider the relationship between the tumor and nearby neurovascular structures. This will allow him or her to inform the patient about sensory and motor deficits that may be expected after a limb-sparing procedure. It is also vital for surgical planning;

Instructions for Physician: Locate the patient's tumor size on the Size axis. Draw a line straight upward to the **Points** axis to determine how many points toward sarcoma-specific death the patient receives for his tumor size. Repeat this process for the other axes, each time drawing straight upward to the **Points** axis. Sum the points achieved for each predictor and locate this sum on the **Total Points** axis. Draw a line straight down to either the Low Grade or High Grade axis to find the patient's probability of dying from sarcoma within 12 years assuming he or she does not die of another cause first.

Instruction to Patient: "If we had 100 patients exactly like you, we would expect between <predicted percentage from nomogram - 8%> and <predicted percentage + 8%> to die of sarcoma within 12 years if they did not die of another cause first, and death from sarcoma after 12 years is still possible."

Figure 5 Positive nomogram for prediction of sarcoma-specific death (SSD) at 12 years postresection for patients with soft tissue sarcoma. Fibro = fibrosarcoma; GR = grade; Leiomyo = leiomyosarcoma; Lipo = liposarcoma; MFH = malignant fibrous histiocytoma; MPNT = malignant peripheral nerve sheath tumor.

nerves, veins, and arteries often limit the extent of the resection to be performed. Whenever possible, vascular structures are skeletonized and major nerves salvaged by resecting perineurium. This will preserve limb function, and if a high-risk lesion is removed with an R1 margin, adjuvant radiation is an option for reducing rates of local recurrence (see below). To avoid amputation when major neurovascular structures are encased by a high-grade tumor, the surgeon may consider advanced maneuvers such as arterial bypass or resection of the sciatic nerve.¹³ Venous reconstruction is rarely indicated and when performed is often not successful; compression garments are used to control postoperative symptoms.

Preoperative diagnoses of dermatofibrosarcoma protuberans (DFSP) and myxofibrosarcoma are of particular concern in planning local resection. These lesions often have microscopic tentacles that extend laterally from the lesion.¹⁴⁻¹⁶

DFSP should be resected en bloc with margins of 2 cm, including the underlying fascia, but underlying muscle rarely needs to be removed as this subtype generally does not penetrate the fascia. Myxofibrosarcoma, however, often penetrates fascia and invades muscle and is often multifocal with skip areas. Therefore, excision should be not only wide laterally but also deep with significant surrounding muscle; again, margins of 2 cm should be resected en bloc with the tumor. With either of these subtypes, more conservative resection leads to a high risk of local recurrence. Although recurrence of DFSP in the surgical bed is a difficult local problem, it is almost never associated with distant spread (unless there is histologic evidence of sarcomatous degeneration). Local recurrence of myxofibrosarcoma, however, is potentially more dangerous as it is associated with a high-grade phenotype in as many as 54% of cases. High-grade

Figure 6 A treatment algorithm for soft tissue sarcoma of the extremity. CT = computed tomography; MRI = magnetic resonance imaging.

recurrence of myxofibrosarcoma places the patient at significant risk for metastatic disease.^{15,16} Therefore, every attempt should be made to resect myxofibrosarcomas with negative margins, even when they appear as low-grade lesions. Multiple procedures may be required to adequately remove all disease, and reconstruction will often require tissue flaps or a skin graft.

SCORE Lymph node metastases are rare in STS and generally occur in the context of epithelioid or clear cell variants of STS.¹⁷ In these cases, sentinel lymph node biopsy has been reported and can give prognostic information as a positive biopsy defines stage III disease. However, this procedure has not been associated with a therapeutic benefit, and no survival advantage has been reported in patients undergoing completion lymph node dissection.¹⁸ For these reasons, the role of sentinel lymph node biopsy in management of STS remains debatable.

Radiation in Extremity STS

SCORE Radiation therapy after limb-sparing surgery for STS appears to increase local control but not survival. This

conclusion comes from three large randomized, controlled trials. In the first trial, 141 patients with STS of the extremity treated with surgery and chemotherapy were randomized to receive postoperative radiation or no radiation.¹⁹ In the context of both high- and low-grade tumors, the addition of adjuvant radiation significantly reduced the risk of local recurrence (risk at 9 years of 33% versus 4% for low-grade tumors and 19% versus 0% for high-grade tumors). However, radiation afforded no benefit in terms of overall survival. Similarly, brachytherapy applied after complete resection of STS in the extremity and superficial trunk improved local control but did not alter disease-specific survival.²⁰ Moreover, local benefit of brachytherapy was restricted to patients who presented with high-grade tumors. Because radiation therapy can have long-term complications such as joint fibrosis and secondary malignancies, the potential risk versus benefit of radiation therapy must be carefully weighed for each patient. Radiation therapy is routinely prescribed for high-risk lesions (> 5 cm and high-grade or recurrent tumors that were not previously treated with radiation) with close margins. Given

the fact that no trial has shown radiation to improve overall or disease-specific survival, it is reasonable to defer adjuvant therapy when the tumor is low grade or the margin is wide, particularly if a local recurrence could be excised without amputation or major functional impairment.

The decision to prescribe radiation therapy is further complicated in that the modality can be administered either preoperatively or postoperatively. A randomized trial compared these strategies by assigning 190 patients with extremity STS to either adjuvant radiation (66 Gy) or neoadjuvant radiation (50 Gy).²¹ This study showed no difference in local control. It did show an increased rate of wound complications in patients treated with radiation prior to resection (35% versus 17%). This difference was most pronounced in patients with STS of the lower extremity. Conversely, patients receiving therapy after resection had a higher risk of long-term fibrotic complications (e.g., joint stiffness), presumably related to the higher dose of radiation.²² Therefore, preoperative radiation therapy can be an excellent choice for patients with tumors adjacent to a joint or tumors located in the upper extremity that are likely to have close or positive margins. In all other settings, the role of radiation therapy is determined from the final assessment of tumor histology, and margin status following resection determines the contribution radiation may play in the multimodality treatment of extremity STS.

Neoadjuvant Chemotherapy

No prospective study has definitively shown a benefit to administration of adjuvant chemotherapy in STS patients. However, three groups of patients should receive neoadjuvant therapy [see Figure 6] because of the high risk of metastasis and/or predicted chemosensitivity of a tumor subtype. The first group includes patients with rhabdomyosarcoma or Ewing sarcoma. Regardless of tumor size, these patients have a high risk of metastasis and are always treated with chemotherapy prior to surgery. The second group encompasses patients with high-grade tumors that are larger than 10 cm. Retrospective studies have demonstrated that neoadjuvant chemotherapy is associated with improved disease-specific survival among these patients.²³ Specifically, neoadjuvant chemotherapy is considered in patients without significant comorbidities and with large, high-grade, round cell liposarcoma, pleomorphic liposarcoma, synovial sarcoma, malignant peripheral nerve sheath tumor, or leiomyosarcoma. However, dedifferentiated liposarcomas, even when they are large and high grade, have a low risk of distant metastasis and are rarely chemosensitive, so initial treatment is surgery when the lesions are resectable.

The third group considered for neoadjuvant chemotherapy includes patients with moderate-size tumors (5 to 10 cm) representing relatively chemosensitive histologies that have a propensity to metastasize. Round cell liposarcoma, pleomorphic liposarcoma, and synovial sarcoma are the most common histologic subtypes treated in this manner.^{24–26}

RETROPERITONEAL AND VISCERAL SARCOMAS

Retroperitoneal Disease

The retroperitoneum is the second most common site of STS, although retroperitoneal lesions are significantly less common than those of the extremity [see Figure 2]. Patients

typically present with a palpable mass or a mass found incidentally on imaging acquired for an unrelated symptom. Patients may have pain and/or symptoms of lower extremity neural compromise. This is particularly true for those with large retroperitoneal tumors, which often remain undetected until they reach sizes greater than 10 cm in diameter. Rarely, patients with retroperitoneal tumors are diagnosed because of paraneoplastic syndromes, such as hypoglycemia related to leiomyosarcoma or solitary fibrous tumor.

A preoperative biopsy is usually needed only if there is suspicion of carcinoma, lymphoma, or germ cell tumor or if the mass appears to be not completely resectable; in other circumstances, biopsy rarely alters the therapeutic plan. Regardless of histologic subtype, the goal of operative intervention is complete gross resection, which can be achieved in 80% of patients. The major hindrance to tumor resectability is involvement of the great or visceral vessels. Retroperitoneal lesions can encase the aorta, vena cava, celiac axis, or porta. In these cases, attempt at resection will leave gross tumor in the surgical bed, and when an R2 resection is anticipated, surgery should be considered only as palliative therapy. Debulking has not been demonstrated to provide survival benefit, and patients with a grossly positive margin have outcomes that are similar to those of patients undergoing no operative intervention [see Figure 7].

Involvement of adjacent organs such as the spleen, pancreas, and bowel does not preclude surgical resection. STS associated with these findings can be managed by en bloc resection to achieve R0 or R1 resection. It should be noted that resection of these organs (excluding the kidney) with STS does increase the morbidity associated with surgery.^{27,28} If the retroperitoneal lesion involves the kidney, adequate resection can often be achieved by removing only the renal capsule with the tumor. This is possible as retroperitoneal tumors rarely invade the renal parenchyma. Involvement of the kidney hilum, however, will require a nephrectomy to obtain adequate margins.

Visceral Disease

The principles that govern surgical resection of visceral sarcomas are similar to those noted above for retroperitoneal tumors. In all instances, a negative resection margin is the goal of operative intervention. The most common subtype of STS in the viscera is GIST; patients present with gastrointestinal bleeding or bowel obstruction. These tumors are generally well circumscribed and can be removed with a 1 cm gross margin; anatomic resection has not been shown to improve outcomes. For example, in most cases, a gastric GIST can be removed with only a small (1 cm) margin of surrounding tissue, preserving the main body of the stomach. Even with large tumors, this approach allows for preservation of visceral organs and minimizes the complexity of reconstruction.

Adjuvant Therapy in Retroperitoneal and Visceral STS

Retroperitoneal lesions are almost exclusively liposarcoma, leiomyosarcoma, or malignant peripheral nerve sheath tumors. These tumors have low rates of response to chemotherapy, and adjuvant chemotherapy has never been demonstrated to improve survival in this patient population. Radiation therapy, however, is more debatable. Several small, retrospective studies have suggested that its use is associated with reduced

SCORE

SCORE

SCORE

SCORE

Figure 7 Disease-specific survival according to extent of resection among patients with retroperitoneal soft tissue sarcoma treated at Memorial Sloan-Kettering Cancer Center over a 25-year period. Outcomes were similar for patients undergoing incomplete gross resection (R2; $n = 93$) and for patients with disease judged unresectable at exploration ($n = 58$).

risks of local recurrence following surgical resection.²⁹ Nevertheless, no difference in overall survival has been implied, and selection bias and significant differences in surgical management between institutions remain confounding factors when interpreting the literature. We do understand that adjuvant radiation administered after resection of a retroperitoneal lesion is associated with significant morbidity. Radiation enteritis occurs in up to 60% of patients and can lead to chronic malnutrition, enteric fistulization, and bowel obstruction.³⁰ Given this drawback of adjuvant radiation therapy, neoadjuvant radiation should be considered if surgical resection is likely to result in positive margins and radiation is to be prescribed. The neoadjuvant approach limits the morbidity of treatment because it can target the radiotherapy to the region at highest risk for microscopic residual disease while limiting the dose to surrounding viscera.

GISTs present a unique case for application of adjuvant treatment because many of them are sensitive to imatinib.

This drug targets the c-kit receptor and is a cytostatic reagent. The effect of adjuvant imatinib therapy in high-risk GIST (at least 3 cm in diameter) has been examined in a randomized, controlled trial.³¹ In patients treated with adjuvant imatinib, recurrence-free survival at 1 year was increased from 83 to 98%. For this reason, the drug is generally administered in the adjuvant setting to high-risk patients. Imatinib is also of use in the neoadjuvant setting.³² It can be prescribed in attempt to reduce the size of the tumor and minimize the morbidity of resection when surgical resection of a lesion will prove morbid. Examples of these cases include lesions located at the gastroesophageal junction or rectal lesions. Imatinib can be prescribed in attempt to reduce the size of the tumor and minimize the morbidity of resection.

RECURRENT AND METASTATIC DISEASE

Following surgical resection of STS, the tumor bed is evaluated by cross-sectional imaging every 4 to 6 months,

depending on the grade of the tumor. Local recurrence is observed in approximately 10 to 30% of patients with extremity STS and 50% of patients with retroperitoneal lesions.³³ At the time of recurrence, patients should again be staged to rule out metastatic disease.

In the context of extremity recurrence, local resectability is determined as above. Important considerations are the post-operative morbidity of limb-sparing surgery and the ability to spare the neurovascular bundle. The surgeon should excise not only gross tumor and a margin of normal tissue but also the prior surgical incision, drain site, and resected specimen bed. Adjuvant or neoadjuvant radiation or chemotherapy may be considered if the patient was not previously treated with these modalities. Local recurrence is associated with poor prognosis when lesions are high grade, recurrences are greater than 5 cm in diameter, and the recurrence-free interval is short (less than 16 months).³⁴ Patients whose disease recurs with these features have an increased risk of disease-associated death and should be considered for neoadjuvant chemotherapy or enrolment in clinical trials.

As in the extremity, retroperitoneal recurrence presents a difficult problem and is associated with a poor prognosis. If the lesion is isolated, surgical resection can again be used in an attempt to achieve a cure, and its goal should be negative margins. Neoadjuvant radiation therapy can be considered. As in extremity recurrence, poor prognostic features include large size of tumor recurrence and short disease-free interval, and patients with these features should be considered for neoadjuvant trials. In addition, retroperitoneal liposarcoma patients with local recurrence growth rates exceeding 1 cm per month have an extremely poor prognosis even after aggressive attempts to completely excise all measurable disease. In a retrospective analysis of such patients, surgical resection was not associated with increased survival. Thus, patients with liposarcoma growth rates greater than 1 cm per month should be considered for systemic treatment with novel targeted therapies or conventional chemotherapy.³⁵

Indications for Metastasectomy

In patients with high-grade STS, surveillance of the surgical bed is accompanied by cross-sectional imaging of the lung, the most common site of metastatic disease (44%). In most patients, metastases are treated with chemotherapy. The choice of agents is dependent on disease histology and is beyond the scope of this review. Resection, however, is often recommended when disease at the primary site is well controlled and the patient presents with isolated pulmonary metastases. Patients most likely to benefit from metastasectomy include those with metachronous disease and long disease-free intervals, those with slowly growing metastases, and those with a limited number of lesions (one to three). Patients with metastatic disease have an overall survival of less than 20% at 5 years, but long-term survival is observed in patients carefully selected for metastasectomy.^{36,37} In these patients, surgery alone may be sufficient for cure as no additional increase in survival has been associated with perioperative chemotherapy.³⁸

DESMOID FIBROMATOSIS

Desmoid tumors are rare neoplasms that develop from mesenchymal stem cells.³⁹ The estimated incidence is only

1,000 cases per year in the United States. Standard management of the disease has included wide resection in the past. Such procedures may be associated with significant morbidity; they can result in short bowel syndrome, incisional hernia, or functional impairment of a limb. Desmoids do not metastasize, however, and this has led to a significant shift in treatment algorithms. Current management strategies do not focus solely on complete eradication of local disease but also on improving functional outcomes for patients with desmoid tumors.

Data supporting current treatment recommendations have been collected only over the last two decades. Large retrospective series showed no difference in the rates of local recurrence following R1 versus R0 resection. This fact was the first that suggested clinicians could adopt a function-preserving approach when planning surgical resection.⁴⁰ Subsequently, in the context of recurrent, nonoperable desmoids, it was observed that the growth of tumors was actually self-limited in some cases. An initial period of observation was, therefore, proposed to be a safe treatment option in patients with recurrent disease.⁴¹ The clear benefit thought to be associated with early surgical resection was questioned.

Most recently, an analysis of 142 patients with primary or recurrent desmoid was reported by Fiore and colleagues.⁴² This study examined cases in which a frontline, nonoperative approach was employed. Eighty-three of these patients did not receive surgery, radiation, or medical treatment at presentation. They were instead followed with serial imaging every 3 to 6 months. The 5-year progression-free survival in this cohort was 49%. For patients who progressed, surgical resection was considered. If resection would result in significant functional impairment or was not technically feasible, a course of medical management with targeted therapies or cytotoxic therapy was prescribed in the neoadjuvant setting or for long-term maintenance. Sorafenib, tamoxifen, cyclooxygenase-2 inhibitors, imatinib mesylate (Gleevec), and anthracyclines (Doxil) are currently employed for this purpose.⁴³ No patient with progressive disease was noted in the study by Fiore and colleagues to have unexpected complications or a poor outcome that could be attributed to an initial period of observation. Given these data, many large sarcoma referral centers now uniformly recommend an initial period of observation before undertaking major surgery in the context of desmoid fibromatosis.

Radiation following resection of desmoids has been advocated in both the adjuvant and neoadjuvant settings. Although several analyses have demonstrated an association between radiation and reduced local recurrence after surgery, no difference in overall survival has been observed.^{44,45} The long-term complications associated with radiation in a patient population, which is generally diagnosed during their second through fourth decade of life, limit its utility. In the context of a disease that has no metastatic potential, this modality is, therefore, almost always reserved for intractable cases that are symptomatic and have failed all other therapeutic options.

Financial Disclosures: None Reported

Desmoid tumors are rare neoplasms that develop from mesenchymal stem cells.³⁹ The estimated incidence is only

9 Benign Breast Disease

*Helen Cappuccino, MD, FACS, Ermelinda Bonaccio, MD, and Swati Kulkarni, MD, FACS**

Clinicians should have an understanding of the evaluation and management of breast disorders. One in two women will consult a health care provider for a breast-related complaint during her lifetime.¹ The fundamental task facing a physician who is evaluating a patient with a breast concern is to determine whether the abnormality is benign or malignant. Even though most breast complaints do not result in a diagnosis of cancer, any woman presenting with a breast complaint should receive a comprehensive evaluation. In this chapter, we focus on the evaluation and management of benign breast conditions.

Screening Recommendations

In the absence of a specific breast complaint, breast cancer can be detected by screening. The three main methods of breast cancer screening are breast self-examination (BSE), clinical breast examination (CBE), and screening mammography.² American Cancer Society (ACS) screening guidelines for women aged 40 years and older specify that mammography and CBE should be included as part of an annual health examination.³ In addition, health care providers should tell women about the benefits and limitations of BSE, stressing the importance of promptly reporting any new breast symptoms. There is currently no role for routine screening ultrasonography or screening magnetic resonance imaging (MRI) in the general population.

BREAST SELF-EXAMINATION

In BSE, the patient inspects and palpates both breasts and axillae. One might assume that instruction in BSE would improve breast cancer detection. However there is no conclusive evidence that BSE is of significant value in this regard. Many self-detected tumors are found incidentally, not during BSE. Furthermore, the best technique for BSE and optimal frequency has not been established. The ASC recommends counseling patients on the benefits and limitations of BSE as a part of the breast cancer screening process that also includes mammography and CBE.³

CLINICAL BREAST EXAMINATION

In CBE, a qualified health care professional carries out a complete examination of the breasts and axillae. As with BSE, there is little evidence indicating that annual or semiannual CBE increases breast cancer detection rates.⁴ Nevertheless, it is prudent for the clinician to include CBE as part of the physical examination performed on every female patient.

* The authors and editors gratefully acknowledge the contributions of the previous authors, Doreen M. Agnese, MD, FACS, Stephen P. Povoski, MD, FACS, and Wiley W. Souba, MD, ScD, FACS, to the development and writing of this chapter.

SCREENING MAMMOGRAPHY

Screening mammography refers to the imaging of asymptomatic women to detect early, clinically occult breast cancers. Mammography is the only breast imaging modality proven to reduce mortality from breast cancer. The Swedish Two-County Trial updated their data in 2000 and demonstrated a 32% reduction in breast cancer mortality in women invited to screening.⁵ Based on the findings from these trials, women should begin annual screening mammography at age 40. There are subgroups of women at high risk for breast carcinoma who may benefit from screening at a younger age, although no randomized controlled trials support these recommendations.⁶ Currently, there is no accepted upper age limit for mammographic screening; however, the presence of significant comorbidities reducing life expectancy to less than 10 years should be considered when ordering a screening mammogram in women over the age of 70.

Digital mammography is becoming more common in many centers. Results from a large prospective multicenter trial comparing digital to conventional film mammography demonstrated no significant difference in cancer detection rates.⁷ However, digital mammography was found to be more sensitive than film in three subgroups: women less than 50 years of age, women with radiographically dense breasts, and women who were pre- or perimenopausal.⁸

Evaluating Breast Complaints and Masses

HISTORY

Evaluation of a woman with a breast complaint should include a thorough history, a physical examination, and appropriate diagnostic studies. A complete history of the current complaint should include onset, duration, and progression of symptoms. Precipitating and ameliorating factors should be noted, as should the relationship of palpable abnormalities, pain, and tenderness to the menstrual cycle. Recent history of trauma to the breast, prior infections, fine-needle aspirations (FNAs), core biopsies, and surgical biopsies should also be recorded. Medical records, including operative reports and corresponding pathology and radiographic reports, should be reviewed carefully. The treating clinician should obtain and review prior breast imaging as part of the patient's history.

Symptoms or complaints involving the breast should be evaluated in the context of historical breast cancer risk data. Historical risk data include (1) history of the duration and type of hormone use (oral contraceptives and hormone replacement therapy); (2) reproductive history (age at menarche, age at menopause, age at first live birth, number of gestations and completed pregnancies); and (3) complete family history of all malignancies on both the maternal and

SCORE the paternal side, including the age at diagnosis. The remainder of the patient's general history should be evaluated with a focus on significant medical problems that may impact surgical planning. Medications and supplements that may contain estrogen-like substances and social history (especially tobacco, alcohol, work, exercise, and even sexual history as it pertains to breast stimulation) can be relevant.

PHYSICAL EXAMINATION

SCORE The breasts should be thoroughly examined in the upright and supine positions. Breast asymmetry and overall appearance of the skin, nipples, and areola should be observed with the patient upright. Any erythema, induration, peau d'orange, nipple retraction, and ulceration should be noted. Occult skin retraction can be demonstrated by having the woman raise her hands above her head and then place them against her hips. Bimanual examination of the breast tissue can facilitate identification of masses in women with dense breast tissue. In the supine position, turning the patient to either side to disperse breast tissue facilitates a more thorough examination for women with larger breasts. For the ptotic breast, palpation of the breast tissue between the thumb and index finger of the same hand may be useful. Location, mobility, and characteristics of masses and thickening should be noted, including size, firmness, presence of smooth or irregular borders, overlying skin changes, consistency, and areas of tenderness. Drawings or digital images can be made to document physical findings. All tissue between the clavicle and costal margins should be palpated, from the lateral sternal border to the posterior axillary line. Patients should also be checked for nipple discharge. Axillary, clavicular, and cervical lymph node basins should also be palpated in the upright and supine positions. The presence of adenopathy, including the size, consistency (hard versus soft), number, laterality, location, and mobility of the lymph nodes, should be documented.

DIAGNOSTIC STUDIES

Diagnostic Mammography and Targeted Ultrasonography

SCORE As mentioned previously, screening mammography refers to imaging of an asymptomatic woman. Diagnostic mammography, on the other hand, refers to imaging a woman with either a clinical complaint (a palpable lump, thickening, focal pain, discharge) or an abnormal screening mammogram. The initial workup of an abnormal screening mammogram involves additional mammographic imaging directed by a radiologist, which determines if the perceived abnormality is a real lesion. Spot and rolled views (with or without magnification) can sometimes demonstrate that the perceived abnormality was actually only the result of overlapping glandular tissue and there is no underlying lesion. The diagnostic mammogram report would then be given a final assessment 1 (negative), and the patient should return to annual screening mammography.

When an abnormality is detected and the patient needs additional mammographic and/or sonographic imaging, the

initial screening mammogram in these patients is given a final assessment 0 [see Table 1]. Women with a Breast Imaging Reporting and Data System (BI-RADS) 1 or 2 should continue to undergo routine annual mammography.⁸ Women with a BI-RADS 3 should undergo short-term follow-up, which typically involves an ipsilateral mammogram in 6 months followed by a bilateral study at 12 and 24 months. A finding in this category should have a less than 2% risk of malignancy based on morphologic and distribution features.^{9,10} Any interval progression at follow-up should prompt a biopsy. Patients with a BI-RADS category 4 or 5 lesion require a tissue diagnosis. As an adjunct to diagnostic mammography, high-frequency breast ultrasonography is often used in the diagnostic workup of a mass and can distinguish between a solid and a cystic lesion. If a solid mass is visualized sonographically, ultrasound-guided core-needle biopsy (CNB) can be performed for pathologic diagnosis.

PERCUTANEOUS CORE BIOPSY

Breast biopsies should be performed percutaneously whenever possible, using stereotactic, ultrasound, or MRI guidance. CNB with an automated gun or vacuum-assisted device has been confirmed in multiple studies to be a reliable alternative to surgical excision.^{11,12} Stereotactic (mammographic) guidance is typically used to biopsy indeterminate or suspicious calcifications as well as masses or densities that are sonographically occult. Ultrasound guidance is used to biopsy masses that can be visualized sonographically and is the most cost-effective type of image-guided core biopsy.¹³ MRI guided CNB is reserved for lesions that are occult to conventional imaging. The benefit of CNB over FNA is that it provides tissue for histologic rather than cytologic evaluation.

With any image-guided approach, it is important to confirm that the pathologic results are concordant with the imaging findings. Treatment decisions should be based on both pathologic findings and the appearance of the abnormality on diagnostic imaging. Discordant imaging and pathologic findings should prompt a surgical biopsy.

OTHER IMAGING MODALITIES

Magnetic Resonance Imaging

MRI is an imaging modality that uses strong magnetic fields to create a cross-sectional image. Breast MRI requires a specific coil and peripheral intravenous injection of a gadolinium-based contrast medium. Contrast-enhanced breast MRI has been shown to have a high sensitivity for detection of invasive breast cancer and can find both invasive and in situ carcinomas that are occult to conventional imaging. In practice, use of breast MRI is predominantly limited to women diagnosed with breast carcinoma and women at increased risk of developing breast cancer.

At present, there is no indication for the use of positron emission tomographic scans in the diagnostic workup of breast diseases outside a clinical trial. A number of new modalities are being investigated, such as positron emission mammography, breast-specific gamma imaging, tomosynthesis, and coned-beam computed tomography. Although some of these modalities are approved by the Food and Drug Administration (FDA), they are not currently standard practice.

Table 1 American College of Radiology Breast Imaging Reporting and Data System (BI-RADS)

Category	Assessment	Description/Recommendation
0	Additional imaging evaluation required	Additional imaging recommended
1	Negative finding	Nothing to comment on; routine screening recommended
2	Benign finding	Negative mammogram, but interpreter may wish to describe a finding; routine screening recommended
3	Probably benign finding	Very high probability of benignity; short-interval follow-up suggested to establish stability
4	Suspicious abnormality	Probability of malignancy; biopsy should be considered
5	Abnormality highly suggestive of malignancy	High probability of cancer; appropriate action should be taken

The report generated after the diagnostic workup is completed will have a final assessment of 1 to 5. The Breast Imaging Reporting and Data System (BI-RADS) lexicon was developed to standardize mammographic reports.⁶ It defines the final assessment categories, which informs the referring physician about the likelihood of malignancy.

General Management of Clinical Findings in the Breast

SCORE+ PALPABLE MASS

A dominant breast mass is defined as a discrete lump that is distinctly different from the surrounding breast tissue. Overall, approximately 10% of dominant breast masses are malignant. The workup and management of a discrete breast mass are governed by the age of the patient, the patient's family and medical history, the physical characteristics of the palpable lesion, and findings on diagnostic imaging.

SCORE+ SOLID MASSES

The likelihood of malignancy is greater when the patient is 40 years of age or older and when the mass is solid, hard, immobile and has irregular borders. Appropriate imaging studies, including mammography and ultrasonography should be done. In women over 30 years of age or with a significant family history of breast cancer, contralateral mammography is indicated to rule out synchronous lesions. If the mass is clinically suspicious, CNB or surgical biopsy should be performed for tissue diagnosis even in the setting of negative imaging.

SCORE+ CYSTIC MASSES

Cysts are a common cause of dominant breast masses, particularly in premenopausal women. They can be differentiated from solid lesions by means of ultrasonography. Sonographically, simple cysts tend to be oval, lobulated, and anechoic, with well-defined borders. Complex cysts with indistinct walls or solid components are more likely to be associated with carcinoma; therefore, imaging-guided aspiration, biopsy, or both should be performed. For asymptomatic simple cysts, no further intervention is required. For symptomatic cysts, FNA is appropriate. If the mass does not disappear completely after aspiration, then biopsy of any residual solid component should be performed. Clear fluid should not be sent for cytologic analysis because of the high likelihood of a false positive result. Bloody fluid obtained from a cyst aspiration should be sent for cytologic examination.

SCORE+ VAGUE THICKENING OR NODULARITY

Normal breast texture is often heterogeneous, particularly in premenopausal women. Vague thickening or tender or nontender areas of nodularity are frequently detected by the

patient or the clinician. It is important to distinguish this vague breast thickening or nodularity from a discrete or dominant breast mass. In clinical practice, the first step in evaluating a nodular area is to compare it with the corresponding area of the opposite breast. Symmetrical tender nodularity—for example, in the upper outer quadrant of both breasts—is rarely pathologic. These areas often represent fibrocystic changes that may resolve with time and thus should be followed clinically. Asymmetrical areas of vague thickening in premenopausal women should be reexamined after one or two menstrual cycles. If the asymmetry persists, the patient should undergo mammography if she is 35 years of age or older and has not undergone a mammogram within the last 6 months. If the mass is clinically suspicious, a surgical biopsy for adequate sampling should be performed even in the setting of negative imaging.

Management of Specific Benign Breast Complaints

MASTALGIA

One of the most common complaints for which a woman seeks a doctor's opinion is mastalgia. Mastalgia (breast pain) can be cyclical or noncyclical and may be idiopathic. Often it is related to other common processes that occur in the breast, such as fibrocystic change or infection. Two thirds of women will complain about mastalgia during the course of their lives.¹⁴ Its cause is poorly understood. A history of the onset and course of the pain are important, especially as it relates to a woman's menstrual cycle. Although rarely a presenting complaint of breast cancer, mastalgia often causes considerable concern for patients. Mastalgia resolves spontaneously in 20 to 30% of cases but can recur in up to 60% of women. Some studies suggest a relationship with caffeine intake, premenstrual syndrome, and serum hormone levels.¹⁵ Frequently, after a complete history and physical examination to rule out a malignancy, the clinician is left treating mastalgia of unknown etiology. Many women respond well to reassurance^{14,16} and simple interventions, such as wearing a properly fitted bra and reducing caffeine intake.

Commonly used remedies, including evening primrose oil, vitamin E, and vitamin B₆, have limited evidence supporting their use to relieve symptoms.^{17,18} If simple interventions are not successful, consideration can be given to pharmacologic agents including nonsteroidal antiinflammatory drugs (NSAIDs), danazol, bromocriptine, and tamoxifen.^{15,18,19} In extreme and otherwise nonresponsive cases, surgical excision of the tender area can be used.²⁰

FIBROCYSTIC CHANGE

Fibrocystic change is often referred to by the misnomer fibrocystic disease. It is a common finding in women who are menstruating, occurring almost exclusively between the ages of 30 and 50. Fibrocystic change is characterized by lumpy or “cobblestone” breasts with ridges of tissue appreciated on palpation. The change is considered a normal variant. If a dominant mass is found in a woman with fibrocystic breasts, diagnostic imaging and biopsy should be undertaken to rule out malignancy. Symptoms generally improve with oral contraceptive use and abate with menopause. Treatment is geared toward symptomatic relief using the agents listed above for mastalgia and reassuring the patient that there is no worrisome etiology or increased risk of developing breast cancer.

NIPPLE DISCHARGE: PAPILLOMAS, DUCTAL ECTASIA, AND GALACTORRHEA

Nipple discharge is the third most common breast complaint after mastalgia and breast mass.²¹ In the majority of cases, the discharge is caused by noncancerous processes, including (1) physiologic discharge, (2) ductal ectasia, and (3) intraductal papilloma. However, malignancy should be ruled out as part of the workup for nonphysiologic discharge.²¹

For women presenting with this concern, the clinician should elicit a history that includes the characteristics of the discharge. The initial question to the patient should be whether the discharge is spontaneous or self-induced. If self-induced, the patient should be counseled to stop eliciting the discharge. If spontaneous, the characteristics are important in determining the cause, including whether it is unilateral or bilateral, milky, bloody, clear, posttraumatic, or cyclical. The history should also include questions pertaining to symptoms associated with an endocrine disorder (hypothyroidism) or to an intracranial etiology such as a pituitary tumor (amenorrhea, visual disturbances, and headache). A history of recent medication changes should also be taken because numerous medications are associated with galactorrhea (H₂ receptor antagonists, antihypertensives, antidepressants, and antidopaminergic agents).²¹

To understand physiologic nipple discharge, an understanding of breast physiology is critical. During pregnancy, high circulating levels of estrogen result in development of the breast into a predominantly glandular structure. With parturition, estrogen production decreases, resulting in prolactin secretion and increased secretory activity, whereas oxytocin results in “letting down” or ejection of milk into the ducts. A suckling infant or similar stimuli (i.e., sexual breast stimulation, postthoracotomy syndrome)²² may result in oxytocin release. Any of these conditions can result in physiologic discharge, which is usually milky and bilateral. Pregnancy can result in galactorrhea from the second

trimester to as late as 2 years postpartum. Elevated thyroid-stimulating hormone (TSH) levels can also be associated with elevated prolactin levels.

Nipple discharge characterized as nonbloody but darker green or brown is associated with ductal ectasia, a benign condition characterized by dilated ducts resulting from obstruction with keratin plugs, and subsequent inflammation and secretions. Ductal ectasia can arise in one or multiple ducts. Dilated ducts are visualized on ultrasonography and on ductography. The characteristics of the discharge from ductal ectasia can be similar to those seen with papillomas and ductal carcinoma in situ (DCIS) and are therefore included in the differential diagnosis of pathologic nipple discharge.

Bloody nipple discharge can appear as bright red, rusty, brown, or green and is considered pathologic. It is characteristically unilateral and emanates from a single duct. Although the most common etiology of this remains a solitary intraductal papilloma, DCIS and invasive breast cancer can also present with pathologic discharge. Of patients presenting with such a discharge, 17% have malignancy, 65% have papillomas, and the remainder have other benign lesions.²³

A thorough physical examination that includes a search for signs of an endocrine disturbance should be conducted (e.g., thyromegaly, visual field defects). As part of the breast evaluation, if nipple discharge is not apparent, the clinician should gently squeeze the nipple to determine whether the discharge is coming from a single duct or multiple ducts and whether the discharge is bilateral. The breast should be evaluated for the presence of a discrete mass that may be associated with an underlying carcinoma.

Historical and physical findings suggestive of an endocrine disorder should prompt the clinician to order TSH and prolactin levels. An MRI of the brain should be ordered to rule out a prolactin-secreting tumor of the pituitary if prolactin levels are elevated. In women of childbearing age, a pregnancy test should also be ordered as part of the workup of galactorrhea. Women with medication-induced bilateral discharge should be counseled about the etiology and reassured.

For patients who are found to have pathologic discharge, the diagnostic workup should begin with bilateral diagnostic mammography. If imaging reveals a focal lesion or microcalcifications, tissue diagnosis should be obtained. Ductography may be able to identify an intraductal lesion and guide surgical planning. Ductography involves cannulating the discharging duct with a small catheter and then injecting a small amount of radiographic contrast medium. Magnified mammographic views are then obtained, and lesions within the duct are identified as either a filling defect or an abrupt cutoff. More recently, ductoscopy, which uses a flexible or rigid fibroscopic ductoscope to cannulate the nipple, can be used to isolate areas of pathology for excision. In skilled hands, it can be combined with (brush) cytology for improved accuracy.^{24,25}

The role of cytologic analysis remains controversial. FNA is also unreliable in evaluating patients with drainage and/or papillomatous disease²⁶ (and many feel that even CNB of endoductal lesions remains inadequate for definitive diagnosis of these lesions).^{27–30} Therefore, surgical excision is recommended given the incidence of concomitant premalignant

and malignant disease in the setting of pathologic nipple discharge.^{27,31} When the location of the intraductal pathology is identified prior to surgical resection, a more limited resection (i.e., single duct excision) of the disease is possible.³² If the duct is peripheral in the breast, the duct can be localized via needle localization. When possible, single duct excision is preferred because it preserves nipple sensation and the ability to breastfeed. In cases where the focal pathology cannot be isolated preoperatively, or in the case of multiduct involvement, a major duct excision is more appropriate. This involves removing all of the central lactiferous ducts and sinuses, preventing further discharge. Both procedures can be done on an outpatient basis and require only local anesthesia and intravenous sedation.

FIBROEPITHELIAL LESIONS: FIBROADENOMA AND PHYLLODES TUMOR

Fibroepithelial lesions encompass a spectrum of breast abnormalities ranging from the fibroadenoma (FA) to the phyllodes tumor (PT). FAs are the most common benign breast lesions and occur most frequently in the second and third decades of life. Their natural history is one of stability or slow growth. Patients will often give a history of a solitary nontender nodule. Physical examination will usually demonstrate a well-defined solitary, rubbery, and mobile nodule. Ultrasonography is particularly useful in younger women and demonstrates a well-defined oval or round hypoechoic mass with discrete margins. Mammography should be obtained (in addition to ultrasonography) in women over 35 years of age and typically demonstrates a well-defined radiopaque mass with smooth borders. If the history, physical examination, and imaging are consistent with an FA, careful clinical follow-up is reasonable with ultrasonography and CBE at 6-month intervals to assess the stability of the lesion. When the diagnosis is uncertain, CNB should be performed. For women who request excision of a benign FA, enucleation of the lesion is adequate. Conversely, if the lesion increases in size during clinical follow-up, surgical excision is recommended to rule out a PT.

PTs are unusual, representing only 0.3 to .5% of breast neoplasms.³³ They have the same clinical appearance and imaging characteristics as FAs, but unlike FAs, they are characterized by a clinical history of rapid growth and have larger dimensions. With increased screening, more PTs are being discovered mammographically. Given that these lesions do not have any features on imaging that would be helpful in differentiating them from FAs, CNB is recommended. However, it can be difficult to differentiate between FA and PT on CNB. A pathologic diagnosis of a fibroepithelial lesion on CNB necessitates excision to rule out a PT. Tumors are classified histologically as low, intermediate, or high grade. Although most PTs have minimal metastatic potential, they have a proclivity for local recurrence and should be excised with at least a 1 cm margin. Local recurrence has been correlated with excision margins but not with tumor grade or size.³⁴ The most common site of metastasis from malignant PT is the lungs.

ATYPICAL DUCTAL HYPERPLASIA, RADIAL SCAR, LOBULAR NEOPLASIA, AND LOBULAR CARCINOMA IN SITU

During the course of a patient's workup for a suspicious physical finding or image-detected abnormality, CNB or

FNA may be performed. A pathologic diagnosis demonstrating atypia (on FNA), atypical ductal hyperplasia (ADH), atypical lobular hyperplasia (ALH), lobular carcinoma in situ (LCIS), or radial scar requires formal surgical excision with needle localization to rule out the presence of invasive carcinoma or DCIS. CNB of these lesions understages findings related to these diagnoses in up to 30% of cases.^{35–39} These lesions may be an independent risk factor for the development of carcinoma³⁸ [see Evaluation of Patients at High Risk for Breast Cancer, *below*].

FAT NECROSIS

Fat necrosis can masquerade as breast cancer. It often presents as a firm, irregular mass within breast tissue, which is occasionally tender. The patient's history is helpful in providing clues to this diagnosis and will often include a history of trauma, reduction mammoplasty, or prior breast surgery. Large cavity size, postoperative hematoma, or infection, as well as adjuvant radiation, can increase the likelihood of fat necrosis. A compromise to the surrounding parenchymal blood supply is thought to be the underlying factor in its development. Diagnostic mammography and ultrasonography can aid in the diagnosis. Loss of speculation, compressibility, oil cysts, and the presence of eggshell calcifications are suggestive of a benign etiology. Review of prior films is necessary to determine the stability of the lesion.⁴⁰ Ultrasonography or stereotactic CNB is appropriate if there is doubt about the diagnosis and will reveal chronic inflammatory cells, lymphocytes, histiocytes, fat necrosis, and saponification. Should the physician opt for short-term clinical follow-up (1 to 2 months) instead of biopsy, it is important to have a patient who will be compliant with keeping follow-up visits.⁴¹

GALACTOCELE

In the pregnant patient with complaints of a mass or tenderness, the clinician should bear in mind the hormonally stimulated status of the breast, resulting in increased tenderness. However, any mass or thickening in the breast requires prompt evaluation in the pregnant patient. Malignancy should always be ruled out, particularly in older, childbearing-age women. A galactocoele, which is a collection of milk within an obstructed, dilated duct, can form during pregnancy, lactation, or recent postlactation. A patient may complain of a tender nodule within the breast tissue. A mammogram will demonstrate a well-circumscribed mixed-density lesion, and ultrasonography will reveal a corresponding partially cystic mass. Simple aspiration can be both diagnostic and therapeutic, providing relief. Malignancy should always be in the differential, particularly in older women of childbearing years.

MONDOR DISEASE

Mondor disease is thrombophlebitis of the superficial veins of the breast. It is characterized by the finding of a tender and often inflamed cord palpated on the patient's breast. After a thorough history and physical examination of the patient's breasts, treatment should consist of NSAIDs, analgesics, and antibiotics. If there is evidence of infection, or should the condition fail to improve, surgical excision is appropriate for definitive management and diagnosis.⁴²

GYNECOMASTIA

SCORE Gynecomastia, or a breast mass in male breast tissue, is usually a benign condition in adolescent males and presents as discoid, subareolar, rubbery thickening of the breast tissue. In the absence of any other findings, such as testicular pathology, or a history of ingestion or use of substances associated with gynecomastia, these patients should be reassured and reexamined. In the case of especially prominent, large, or symptomatic gynecomastia, surgical excision is reasonable. In the mature male population, a physical examination and history are vitally important. Soft, diffuse enlargement is a result of medication in 20 to 25% of cases.⁴³ Gynecomastia can also be due to hormonal, physiologic, or idiopathic factors and can usually be managed nonoperatively and with serial examinations. Many medications resulting in gynecomastia are felt to do so by elevating prolactin levels comparatively. If the gynecomastia is attributable to medication, switching the patient off the medication will often result in regression over the course of a few months. For men who would like to avoid surgery, some success has been noted in treating gynecomastia with tamoxifen, raloxifene, and aromatase inhibitors.^{44,45} However, a finding of a solitary hard mass, especially with findings of adenopathy and skin changes, requires aggressive workup, including mammogram and tissue diagnosis, usually with CNB.

SKIN AND NIPPLE CHANGES

SCORE Common breast skin and nipple changes include bacterial infections (mastitis, cellulitis, with or without underlying abscess), fungal infections, and dermatitis. In lactating women, mastitis is generally the result of poor hygiene. Women will often give a history of an abrasion or crack in the nipple. Symptoms typically include erythema, tenderness, and swelling of the breast. *Staphylococcus aureus* is the most common organism identified. Treatment involves continued breastfeeding and antibiotics. The choice of antibiotics should take into consideration the safety of the breastfeeding infant.⁴⁶

SCORE Nonresolution of the infection with a course of appropriate antibiotics should prompt the surgeon to consider the presence of an underlying abscess or an antibiotic-resistant organism. Fluid from an abscess should be sent for Gram stain and culture to ensure the appropriate choice of antibiotic. If the symptoms persist in the absence of the above causes, inflammatory breast cancer should be considered, followed by appropriate imaging, punch biopsy of the skin, and percutaneous biopsy of any underlying lesion.

SCORE In nonlactating women, cellulitis of the breast typically occurs in the lower half of the breast and is more commonly found in women who are overweight, have large, pendulous breasts, or have poor personal hygiene. Breast abscesses are more frequently seen in women with a history of diabetes, rheumatoid arthritis, chronic steroid use, chronic granulomatous lobular mastitis, and trauma.⁴⁶ Treatment includes antibiotics and identification of an underlying abscess followed by aspiration or drainage. Aspiration should always precede

drainage. Intravenous antibiotics should be considered for women with elevated temperature and white blood cell count. Other skin conditions in the breast include sebaceous cysts and hidradenitis suppurativa. Appropriate antibiotics should be given, and surgical excision is often required for resolution of the symptoms. Fungal (candidal) infections involving the breast are a common complaint in women with large, pendulous breasts. The lower breast and inframammary crease are common locations for the characteristic erythematous moist patches. Treatment includes keeping the area clean and dry and topical antifungal powders or creams.

In nonlactating women, benign processes involving the nipple are often the result of trauma or damage to the nipple or subareolar ducts. Smoking is associated with periductal mastitis, which can present with pain, inflammation, nipple retraction, and discharge. Appropriate antibiotics and abscess aspiration or drainage are the recommended treatments. Trauma, dry skin, or dermatitis can lead to excoriation of the nipple. Allergic or atopic dermatitis frequently occurs as a result of allergies to clothing, dyes, perfumes, and detergents. Treatment is symptomatic, with removal of the offending agent and a course of topical steroids. Short-term clinical follow-up (1 to 2 weeks) is essential to ensure resolution of the symptoms. Breast cancer, including Paget disease of the nipple, can present with these symptoms, and it is vital that the surgeon make an accurate diagnosis. If there is no improvement of the symptoms in 2 weeks, punch biopsy of the nipple should be done.

Evaluation of Patients at High Risk for Breast Cancer

Significant morbidity and cost are associated with breast cancer treatment. Approximately one third of women diagnosed with breast cancer will succumb to the disease. This has led to efforts to provide primary prevention to high-risk women. A number of factors have been identified that increase breast cancer risk [see Table 2].⁴⁷ These risk factors include (1) mutations in genes that confer a predisposition to breast

Table 2 Magnitude of Known Breast Cancer Risk Factors

Relative risk < 2
Early menarche
Late menopause
Nulliparity
Age > 35 first birth
Hormone replacement therapy
Obesity
Alcohol use
Proliferative breast disease
Prior breast biopsies
Relative risk 2–4
One first-degree relative with breast cancer
Radiation exposure
Prior breast cancer
Mammographic density
Relative risk > 4
Two first-degree relatives with breast cancer
Gene mutation
Lobular carcinoma in situ
Ductal carcinoma in situ
Atypical hyperplasia

Adapted from: Morrow M, Jordan VC. Managing breast cancer risk. 1st edition. Hamilton, ON: BC Decker Inc; 2003. p. 302.

cancer⁴⁸; (2) hormonal and reproductive factors^{47,49–51}; (3) environmental factors, including diet and lifestyle characteristics of developed Western nations⁵²; (4) prior radiation to the chest wall as a teenager or young adult⁵³; (5) a history of prior breast cancer, radial scar, or other premalignant lesions^{37,54,55}; and (6) increased mammographic density.⁵⁶ Recognition of factors that increase breast cancer risk facilitates appropriate screening and clinical management of individual patients. It must be recognized, however, that most women have none of the known risk factors for breast cancer, and the absence of these risk factors should never prevent full evaluation or biopsy of a suspicious breast lesion.

Approximately 10% of all breast cancers are hereditary.⁵⁷ Hereditary breast cancer is characterized by early age of onset, bilateral disease and disease in other organ sites. Therefore, an accurate and complete family history, including all malignancies, is essential for quantifying a woman's genetic predisposition to breast cancer. Questions about breast cancer in family members should go back several generations, with age at diagnosis recorded if available. Any personal history of cancer should be recorded, with particular attention paid to breast, ovarian, and endometrial cancers.

BRCA1 and *BRCA2* account for the majority of hereditary breast cancers. The lifetime risk of breast cancer in these individuals can be as high as 85%. Mutations in these genes are associated with other malignancies, most notably ovarian, pancreatic, and prostate cancer. Specific founder mutations in *BRCA1* and *BRCA2* occur within certain ethnic groups (e.g., Ashkenazi Jews).⁵⁷ Surgeons should also be aware of mutations in other genes that are commonly associated with an increased risk of breast cancer, including mutations in *p53* (Li-Fraumeni syndrome), mutations in the *PTEN* gene (Cowden syndrome), and hereditary diffuse gastric cancer syndrome (*CHD1*). Tests that detect mutations in these genes are commercially available. Clinicians should consult a licensed genetic counselor to determine appropriate candidates for testing.

Genetic testing has significantly improved our ability to define breast cancer risk for the subset of women who have a mutation. For women without a known genetic predisposition, the Gail⁵⁸ and Claus models⁵⁹ are two tools that can screen women who may be at increased risk and would therefore benefit from enhanced surveillance and chemoprevention. It should be noted that these mathematical models define population-based risk, not individual risk.

Histologic markers of risk include both ductal and lobular atypia, radial scar, and lobular carcinoma in situ (LCIS). Atypia and radial scar confer a fourfold increased risk of developing breast cancer.^{60,61} LCIS is associated with an increased lifetime risk of subsequent carcinoma between 20 and 25%. Pleomorphic LCIS, a pathologically distinct entity of LCIS, appears to be associated more frequently with invasive cancer.^{62,63} At present, women with these high-risk lesions should be offered screening and chemoprevention.

Currently, there are three options for women to manage their risk: (1) enhanced surveillance, (2) chemoprevention, and (3) prophylactic mastectomy. For women with LCIS or a family history of breast carcinoma, surveillance should include twice-yearly CBE. Mammography should be performed annually after the diagnosis of LCIS or atypical hyperplasia. Women with a family history of breast cancer

should have screening mammography performed annually, beginning 10 years before the earliest age at which cancer was diagnosed in a first-degree relative.⁶⁴ For women with known genetic mutations and other women from families with an autosomal dominant pattern of breast cancer transmission, annual mammographic screening should begin at age 25.⁶⁴ There are several prospective nonrandomized trials which were designed to assess the benefit for adding yearly screening breast MRI for women at high risk for breast cancer.^{65–69} These studies demonstrated that breast MRI is more sensitive than mammography. The ACS recently published recommendations for the use of screening breast MRI as an adjunct to mammography. Annual screening with breast MRI is recommended for the following: (1) *BRCA* mutation carriers; (2) first-degree relatives of a *BRCA* mutation carrier who have never been tested; (3) women with a lifetime risk of 20 to 25% based on risk models that are predominantly dependent on family history; (4) women with a history of radiation to the chest between the ages of 10 and 20 years; (5) women with Li-Fraumeni syndrome (mutations in the *p53* gene) and their first-degree relatives; and (6) women with Cowden and Bannayan-Riley-Ruvalcaba syndromes (mutations in the *PTEN* gene) and first-degree relatives.⁷⁰

It is important to remember that although the sensitivity of breast MRI for cancer is high, the specificity is relatively low and can result in high recall and biopsy rates.⁷⁰ Breast MRI should be used as an adjunct to mammography and not a replacement. Mammography and MRI can be done simultaneously or alternating with each other at 6-month intervals to coincide with the CBE. Given the specificity of breast MRI and the fact that many enhancing lesions seen on breast MRI are occult to conventional imaging modalities, it is essential that any facility performing screening breast MRI should have the capability for MRI-guided breast biopsy.

Chemopreventive strategies are designed either to block the initiation of the carcinogenic process or to prevent (or reverse) the progression of the premalignant cells to an invasive cancer.⁷¹ Only tamoxifen and raloxifene are currently FDA approved for chemoprevention in breast cancer. Both are selective estrogen receptor modulators (SERMs). Large multicenter randomized trials demonstrated the efficacy of these agents in the primary prevention setting for women at increased risk of breast cancer based on a Gail score of 1.67 or a personal history of ADH or LCIS. The overall risk of invasive breast cancer was reduced by 50% after treatment for 5 years and limited to estrogen receptor (ER)-positive breast cancers in these high-risk women. Raloxifene is currently approved only for postmenopausal women and has the added benefit of treating postmenopausal osteoporosis. It is noteworthy, however, that raloxifene was not found to prevent noninvasive breast cancers in this trial.⁷²

The hot flashes, deep vein thrombosis, and endometrial cancer associated with tamoxifen have made it an unattractive option for many women. This has generated interest in identifying other chemopreventive agents. Aromatase inhibitors, which are used to treat ER-positive breast cancers in postmenopausal women, reduce the risk of contralateral cancers and may have a role to play in chemoprevention. In addition, gonadotropin-releasing hormone agonists, monoterpenes, lignans, retinoids, rexinoids, vitamin D derivatives,

and inhibitors of tyrosine kinase are all undergoing evaluation in clinical or preclinical studies with a view to assessing their potential chemopreventive activity. Whether any of these compounds will play a clinically useful role in preventing breast cancer remains to be seen.

For those women at significant risk of breast cancer attributable to genetic predisposition, bilateral prophylactic mastectomy can be considered. High-risk women who underwent this procedure, compared with those who did not, had their breast cancer risk reduced by at least 90%.⁷³ Oophorectomy also confers up to a 50% breast cancer risk reduction in premenopausal women.⁷⁴ The benefits of prophylactic

mastectomy must be weighed against the irreversibility and the psychosocial consequences of the procedure.

Research involving high-risk women is challenging because of the large numbers of women who must be recruited and followed for many years and because of the cost associated with such an undertaking. Improved risk assessment tools that can aid in improved risk stratification are under active investigation.⁷⁵ Current trials are focused on identifying and using intermediate biomarkers of breast cancer risk to test potential chemopreventive agents.

Financial Disclosures: None Reported.

1 DYSPHAGIA

P. James Villeneuve, MDCM, PhD, FRCSC, and R. Sudhir Sundareshan, MD, FRCSC, FACS*

The term *dysphagia*, derived from the Greek *dys-* (with difficulty) and *-phagia* (to eat), describes difficulty in the transfer of food or liquid boluses from the mouth to the stomach. Dysphagia is a common complaint, with at least 35% of patients above the age of 50 complaining of weekly dysphagia and up to 60% of nursing home residents suffering feeding difficulties as a result of dysphagia.^{1,2}

There are two forms of dysphagia. Oropharyngeal dysphagia results from a functional impairment in the initiation of swallowing, including the oral and pharyngeal phases [see *Sidebar Normal Swallowing Mechanism*], and often results from systemic neurologic or myopathic syndromes [see *Table 1*]. Esophageal dysphagia relates to intrinsic functional (motor) and anatomic abnormalities of the esophagus that result in swallowing difficulties [see *Table 2*].^{1,3}

This chapter outlines the basic physiology of the swallowing mechanism and proposes an evaluative and diagnostic approach to difficulties with swallowing. The technical details of specific procedures employed in the definitive treatment of certain causes of dysphagia are described in later chapters of this volume.

Evaluation

A systematic approach to the patient with dysphagia is mandatory. A thorough history and complete physical examination allow for an accurate assessment of likely etiologies. Confounding diagnoses, such as angina pectoris, thyroid goiter, and pharyngitis, should be eliminated.

IMPORTANT ELEMENTS TO ELICIT ON HISTORY

Timing of Dysphagia

Immediate coughing, choking, or regurgitation suggests oropharyngeal causes for dysphagia. A sensation of food “sticking” or getting “caught” or the delayed regurgitation of food suggests esophageal causes of dysphagia.² Patients reporting the constant presence of symptoms not associated with swallowing difficulties may have globus sensation, which is a benign, nonpainful fullness in the neck or throat.⁴

Painful Swallowing

Odynophagia is not typically associated with dysphagia; its presence should prompt consideration of infectious or inflammatory etiologies. Exposure and ingestion of caustic

substances must be sought out as an expedient assessment of severity and consideration of immediate surgery must be made.

Location

Patients will self-localize symptoms to the cervical, retrosternal, or epigastric regions. Studies have demonstrated accurate localization, by patient history, to within 4 cm of the culprit lesion in up to 74% of cases.⁵ Accuracy seems best for proximal lesions.

Solid or Liquid

Intolerance to both liquids and solids suggests a functional or neuromuscular cause of dysphagia. Difficulties with solid food only strongly implicates a mechanical or anatomic causes of dysphagia⁶; a progression from purely solid food dysphagia to both solid and liquid dysphagia suggests narrowing attributable to an evolving mechanical obstruction.

Onset and Progression

The temporal pattern of symptom onset and duration also gives valuable information as to possible causes for dysphagia. Intermittent, nonprogressive symptoms suggest an intrinsic motor dysfunction (such as diffuse esophageal spasm) or a mechanical cause such as a web or ring. If the symptoms have been present for a short period of time or are rapidly progressive, a malignant etiology must be ruled out.

Associated Symptoms

A history of anorexia or weight loss suggests an underlying malignancy. Passive regurgitation of food particles may arise from achalasia or a cricopharyngeal diverticulum. Retrosternal chest pain, once cardiac etiologies have been eliminated, may be present in cases of esophageal spasm or gastroesophageal reflux. However, dysphagia secondary to peptic strictures and adenocarcinoma are without symptoms of gastroesophageal reflux disease (GERD) in up to 25 to 35% of cases.⁷ Medication lists must be examined to rule out culprit medications (alendronate, doxycycline, nonsteroidal antiinflammatory drugs [NSAIDs], and mycophenolate mofetil [MMF]) that may cause drug-induced esophageal injury.⁸

PHYSICAL EXAMINATION

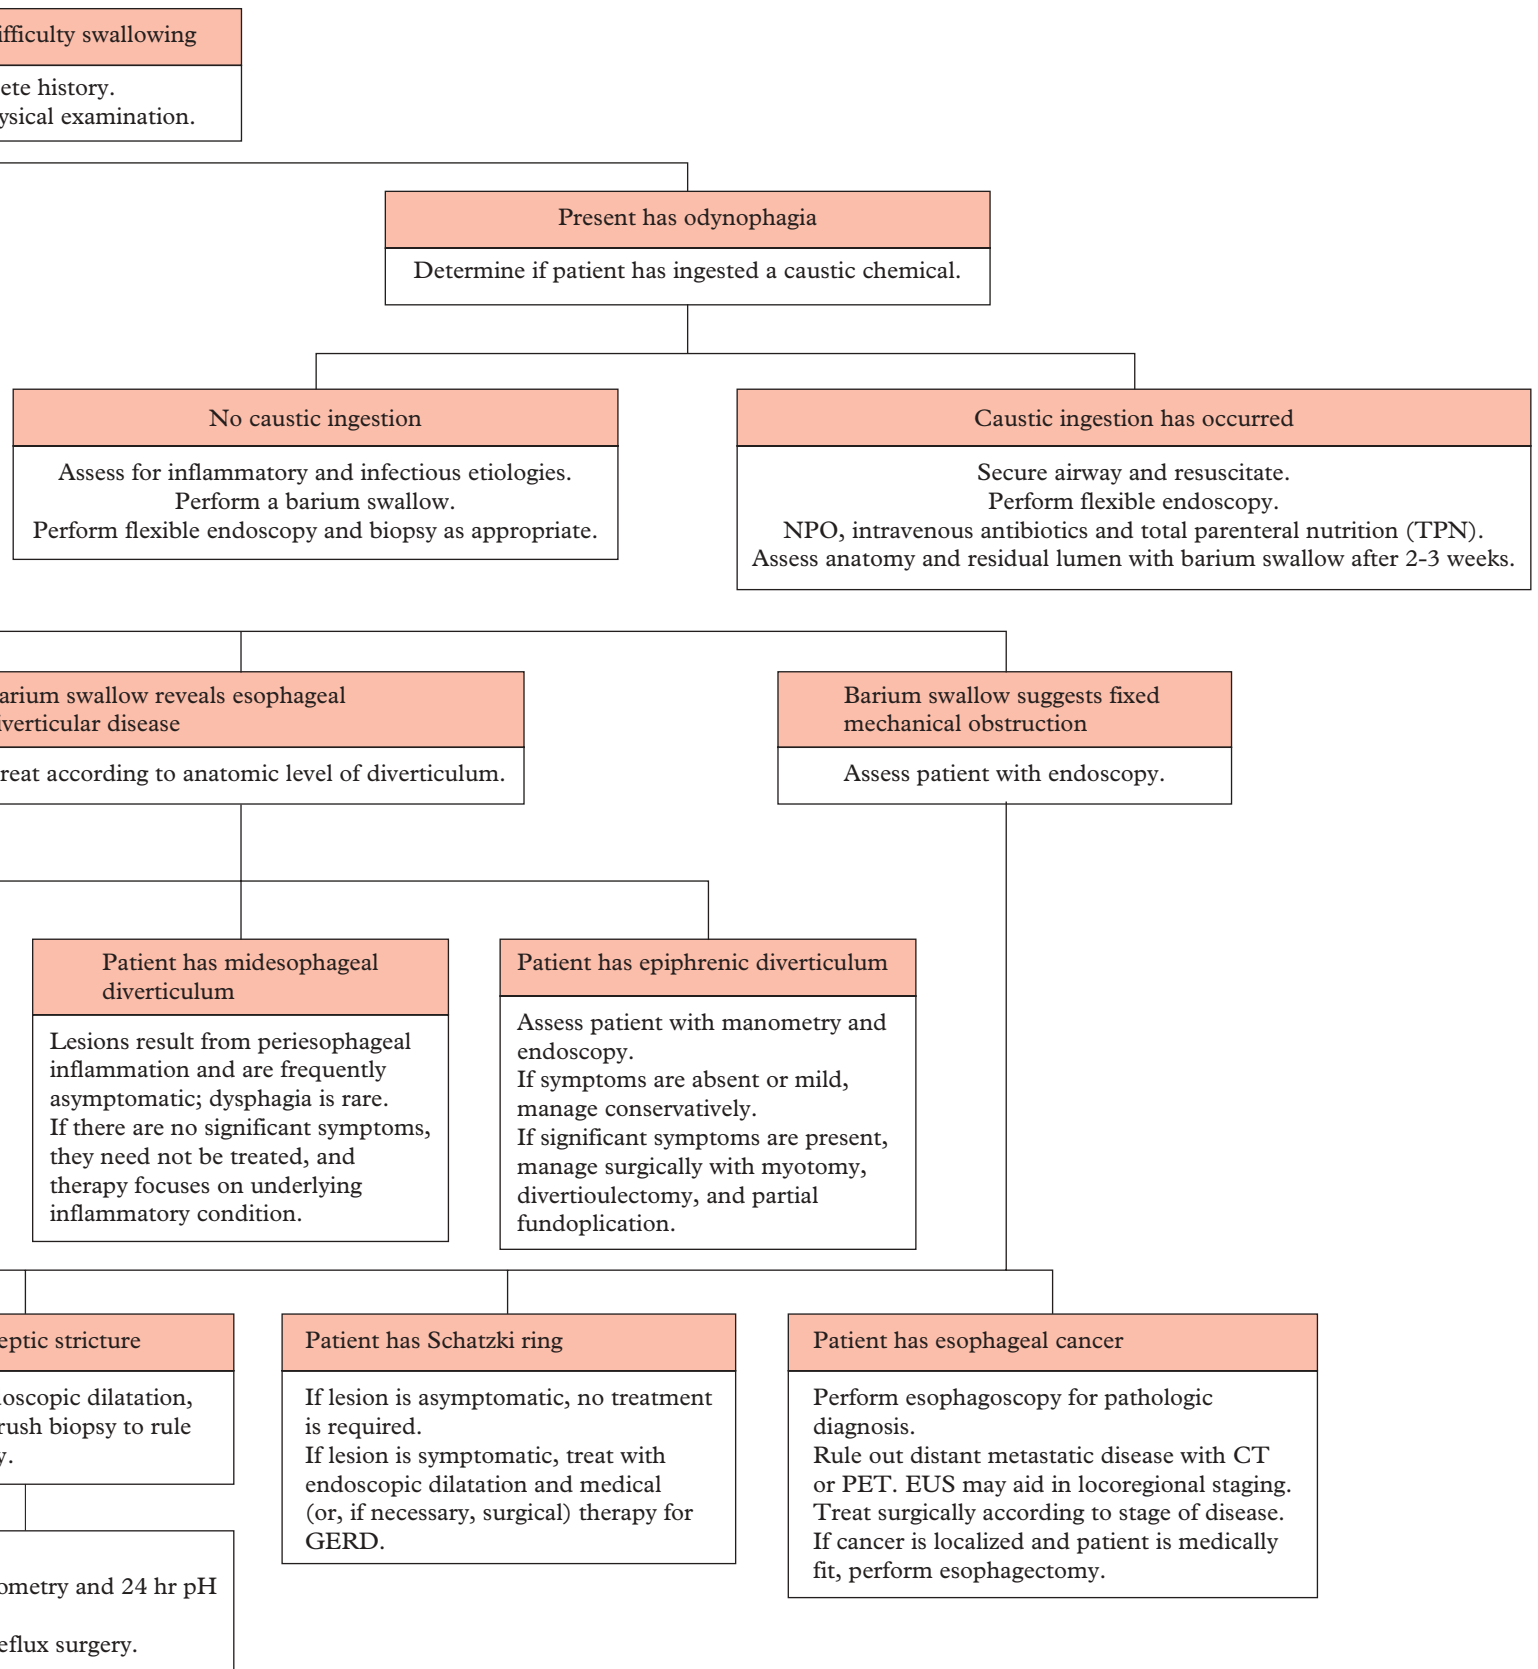

The esophagus is a deep-seated structure that does not lend itself to direct physical assessment. Although a thorough physical examination should follow a complete history, information gathered is useful only in inferring potential diagnoses. A detailed and accurate history is the mainstay of clinical assessment in patients who present with dysphagia.

The head and neck are examined for the size of the thyroid gland, as well as for the presence of any lymphadenopathy or masses. A careful examination of cranial nerves may

DES = diffuse esophageal spasm; LES = lower esophageal sphincter; GERD = gastroesophageal reflux disease; PPI = proton pump inhibitor; NPO = nil per os; CT = computed tomography; PET = positron emission tomography; EUS = endoscopic ultrasound.

Normal Swallowing Mechanism adapted from Matsuo and Palmer²⁵

Swallowing was previously described using a three-phase sequential model, whereby the position of the food bolus was used to identify the oral, pharyngeal, and esophageal phases. Later reports expanded this into a four-stage model by dividing the oral phase into preparatory and propulsive stages. These early models accurately depicted liquid swallows but were inadequate to model solid food boluses. The process model accounts for swallowing of solid foods by expanding the oral phase into stage I, transport, food processing, and stage II, transport. The pharyngeal and esophageal phases are common to both liquid and solid transport.

Oral Phases of Liquid Swallowing

Preparatory	Liquid is held against hard palate by tongue and sealed posteriorly by contact between tongue and soft palate
Propulsive	Sequential contact between tongue and hard palate coupled with relaxation of seal between posterior tongue and soft palate squeezes liquid into pharynx

Oral Phases of Solid Swallowing

Stage I transport	Food is positioned against occlusive tooth surfaces by tongue movement.
Oral food processing	Coordinated movements of the jaw, in concert with the tongue, cheek, soft palate, and hyoid bone movement. This results in masticated, moistened food that is optimal for further swallowing.
Stage II transport	Food bolus is positioned on the tongue surface. Sequential contact between the tongue and hard palate coupled with relaxation of seal between posterior tongue and soft palate propels food into the pharynx.

Pharynx

Upper Esophageal Sphincter

Upper esophagus

Middle esophagus

Lower esophagus

Lower Esophageal Sphincter

Pharyngeal Phase

This rapid phase must achieve airway protection while facilitating passage of boluses through the upper esophageal sphincter (UES) to the esophagus proper. Airway protection is achieved by concerted closure of the vocal cords and laryngeal movement (anteriorly and superiorly) with concomitant tilting of the epiglottis to seal the laryngeal vestibule. Food propulsion follows: the soft palate rises to block retrograde passage into the nasopharynx. Pharyngeal constrictors sequentially contract from cranial to caudal, shortening the pharynx and propelling the food bolus downward. This “pharyngeal pump” can generate pressures of up to 200 mm Hg. The UES has a resting pressure of between 16 and 118 mm Hg and is closed at rest. Active opening of the UES is achieved by relaxation of the cricopharyngeus, traction by the strap muscles, and distending pressure of the descending food bolus.

Esophageal Phase

Both the UES and the lower esophageal sphincter (LES) remain closed at rest to prevent reflux. Autonomic efferent signals mediate peristalsis; an initial wave of relaxation preceding the food bolus is followed by a wave of contraction, resulting in transit through the esophagus into the stomach. *Primary* esophageal peristalsis is triggered by voluntary swallowing but autonomously propagates at 2 to 5 cm/s through the striated muscles of the upper third of the esophagus, slowing as peristalsis passes into the smooth muscles of the lower esophagus. Secondary esophageal peristalsis is involuntary and arises in response to esophageal distention or irritation. It is thought that these waves of peristalsis serve to keep the esophagus clear. Tertiary esophageal waves can arise normally between swallows but are often nonpropulsive.

The sidebar figure demonstrates normal waveforms and propagation of peristalsis in swallowing. It is evident that coordination between the different anatomic levels of the esophagus is required for effective swallowing. The high-pressure contraction in the pharynx is coordinated with full relaxation of the UES. This allows transfer of swallowed material into the esophagus proper, where peristaltic pressures of up to 80 mm Hg are noted. Orderly progression of moderate-amplitude waves through the esophageal body occurs. The LES relaxes early in response to swallowing and slowly regains its resting pressure of 10 to 25 mm Hg in concert with distal esophageal transport.

demonstrate deficits contributing to oropharyngeal dysphagia, and corresponding neurologic assessment may reveal signs of a cerebrovascular accident (CVA), myasthenia gravis, or Parkinson disease. The chest and abdomen are examined for the presence of subcutaneous nodules or masses that may indicate underlying malignancy. Dermatologic rashes may

indicate a paraneoplastic syndrome or a primary autoimmune disorder. Murmurs or thrills on cardiac auscultation may represent atrial enlargement (secondary to mitral valvular stenosis), causing extrinsic esophageal compression. Refer to *Table 1* and *Table 2* for specific causes of oropharyngeal and esophageal dysphagia.

DIAGNOSTIC TESTS

Many diagnostic tests can be used to assess dysphagia, including endoscopic, radiologic, and manometric modalities. The application of these should be predicated by the history.

In cases of suspected or confirmed caustic ingestion, the first test is emergent upper flexible endoscopy to assess the anatomic extent of damage and to grade the injury.⁹ In all other cases of dysphagia, the barium swallow is the ideal first test as it is readily available, cost-effective, and rapidly performed. Information can be gained from the barium study regarding anatomic relations, esophageal transit patterns, and the presence or absence of mass lesions and diverticulae. The safety and diagnostic yield of subsequent upper endoscopy are enhanced.

Upper endoscopy allows for a visual assessment of mucosa; diagnostic and therapeutic maneuvers such as biopsies, brushings, and dilatations can be performed.

Endoscopic ultrasonography (EUS) is an emerging diagnostic modality that allows for assessment of the esophageal wall and surrounding tissues. This permits the characterization of esophageal masses (depth of invasion, T stage) and an assessment of adjacent lymphadenopathy (N stage), and guides endoscopic fine-needle aspiration biopsies. EUS-guided biopsies have excellent predictive value in the assessment of lymph node involvement in cases of esophageal carcinoma.¹⁰

CMV = cytomegalovirus; GERD = gastroesophageal reflux disease; HSV = herpes simplex virus.

When reflux disease is suspected, extended pH monitoring is invaluable in assessing the presence and severity of GERD. Motility disorders are best diagnosed using manometric techniques.

In cases where extrinsic compression is suspected or demonstrated, cross-sectional imaging using computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in identification of malignant masses or vascular anomalies (aberrant subclavian vessels, aortic aneurysms, or Kommerell diverticulae).^{11,12} Dysphagia lusoria is a rare entity in which dysphagia results from extrinsic vascular compression of the esophagus from an aberrant right subclavian artery, which arises from the thoracic aorta and typically courses posterior to the esophagus [see Figure 1].

The assessment of esophageal cancer also requires cross-sectional imaging with CT and fluorodeoxyglucose-positron emission tomography (PET). The use of PET is highly sensitive for the detection of unsuspected metastatic lesions in patients deemed candidates for curative resection on the basis of CT alone.¹³

Management of Esophageal Dysphagia

MOTOR DISORDERS

Motility disorders affect the smooth muscle of the distal esophagus and the lower esophageal sphincter (LES). Symptoms typically include dysphagia to solids and liquids; noncardiac chest pain may also be present.

Achalasia

Ninety-eight percent of all cases of achalasia are idiopathic. The disease is thought to result from a loss of inhibitory neurons in the Auerbach

plexus, altering neural input to the LES and preventing normal relaxation.¹⁴ Achalasia affects females and males equally at a rate of 1 per 100,000 individuals per year. The usual presentation is between 20 and 50 years, but it has been described in all age groups. The disease is slowly progressive, and presentation is typically at advanced stages. Symptoms include progressive dysphagia to both solids and liquids, accompanied by regurgitation of food particles, chest pain, and weight loss. GERD-like symptoms were present in up to 48% of patients in a study of 32 patients¹⁵; these symptoms are a consequence of stasis esophagitis (secondarily to fermentation of retained food) rather than reflux of gastric acid.

Plain x-rays may reveal an air-fluid level in the distal esophagus, and a barium swallow will demonstrate a dilated and atonic esophagus with the pathognomonic “bird’s-beak” narrowing of the gastroesophageal junction (GEJ) [see Figure 2]. Long-standing achalasia may manifest with an extremely dilated and tortuous esophagus (often described as a sigmoid esophagus) [see Figure 3]. Manometric findings of aperistalsis and failure of LES relaxation are key in establishing the diagnosis. Resting LES pressures may be normal or elevated. Endoscopic assessment is required to visually assess mucosal appearance to rule out cancer.

Figure 1 Dysphagia lusoria. Contrast-enhanced CT scan of the upper chest at the level of the clavicular heads (a) and near the carina (b) demonstrating the retroesophageal course of the right subclavian artery (arrow) causing compression of the esophagus (arrowhead) against the trachea (T) and right carotid artery. One can appreciate the idea of a “vascular ring” in such cases causing esophageal compression.

Treatment modalities for achalasia must achieve enhanced LES compliance and lower resting LES pressures. Medical management with calcium channel blockers or nitrates has no meaningful benefit. Endoscopic management includes endoscopically injected botulinum toxin, or balloon dilatation, to mechanically disrupt the lower esophageal muscle fibers. Recurrent dysphagia (up to 50%) has been noted in some studies at 5 years after balloon dilatation, with a 5% periprocedural risk of esophageal rupture.¹⁶ In comparison, a laparoscopically performed Heller esophagomyotomy with partial anterior (Dor) fundoplication is considered to be the standard of care in terms of both durable outcomes (90 to 95% resolution of dysphagia) and low complication rates.¹⁴

Long-standing achalasia is a risk factor for esophageal squamous cell carcinoma, and tumors of the GEJ may present with symptoms similar to those of achalasia.

Dysmotility Syndromes

Motility disorders can be considered within a spectrum that includes diffuse esophageal spasm (DES), nutcracker

esophagus, and hypertensive LES. These disorders are traditionally considered separate entities; however, the manometric findings and the mainstays of medical treatment are similar.

DES is a dysmotility syndrome of unknown etiology. It is characterized in 50% of patients by intermittent dysphagia to solids and liquids. Up to 5% of patients with unexplained chest pain are found to have DES on manometric testing.⁷ Evidence for DES on manometry includes periodic prolonged, multi-peaked, high-amplitude contractions in more than one in five wet swallows, with observation of normal peristalsis in intervening periods. Incomplete LES relaxation or hypertensive LES may also be observed. Figure 4 demonstrates the classic corkscrew appearance that is observed in some cases of DES.

Nutcracker esophagus presents more commonly with chest pain rather than dysphagia. Manometry also forms the

Figure 2 Achalasia. Barium swallow demonstrates the proximal dilatation and classic “bird’s beak” narrowing at the esophagogastric junction, consistent with achalasia, in a 22-year-old woman being evaluated for dysphagia.

mainstay of diagnosis: a normal peristaltic pattern is noted, with extremely increased pressure amplitudes of more than 180 mm Hg. In contrast to DES, normal peristalsis is not observed within trains of high-pressure waves. Barium swallow is of normal appearance.

Hypertensive LES may be found in isolation but often coexists with other dysmotility syndromes. Resting pressures at the LES by manometry are found to be 45 mm Hg or greater.

Treatment for DES, nutcracker esophagus, and hypertensive LES is based on smooth muscle relaxation using nitrates such as isosorbide dinitrate or calcium channel blockers such as diltiazem. Balloon dilatation may be effective for isolated hypertensive LES.

Esophageal Diverticulae

Diverticulae are classified according to the degree to which the esophageal wall is involved in the outpouching: true

Figure 3 Sigmoid esophagus. Barium study demonstrates dilated esophagus with right-sided deviation and tortuous course of the distal esophagus. Treatment most often involves resection of diseased esophagus with conduit interposition.

diverticulae involve all layers of the esophageal wall, whereas false diverticulae involve only the mucosal layer. Both types of diverticulae can also be classified by the

mechanism underlying their formation: True diverticulae usually form in the midesophagus and are most often related to extrinsic traction from extramural inflammation in adjacent mediastinal lymph nodes. These are also referred to as traction diverticulae. False diverticulae relate to dysmotility and consist of the mucosa being extruded through external muscular layers above a high-pressure zone and are thus pulsion-type diverticulae.

Intramural pseudodiverticulosis is a rare cause of dysphagia characterized by multiple outpouchings of the esophageal wall; these outpouchings represent the dilatation of submucosal glands.¹⁷ Although a benign condition, complications related to infection, inflammation, perforation, stricture, and bleeding have been reported. The mainstay of treatment is reduction of inflammation and dilatation of strictures as necessary.

Pharyngoesophageal diverticulae (Zenker diverticulum) are the most common diverticulae observed. These pulsion-type false diverticulae arise in the Killian triangle and are located just superior to the cricopharyngeus muscle. The

Figure 4 Diffuse esophageal spasm. The classic corkscrew appearance of the esophagus is evident in this barium study in a middle-aged patient presenting with dysphagia and intermittent chest pain.

basis for the formation of a Zenker diverticulum is pharyngo-cricopharyngeal dyscoordination. When the cricopharyngeal sphincter fails to immediately and fully relax during swallowing, the pharyngeal pump mechanism produces extremely high pressures. As a result of these high pressures, progressive bulging of the mucosa occurs in the posterior midline through a potential gap between the pharyngeal constrictors and the cricopharyngeus muscles (the Killian space). There has been a long-standing appreciation of an association between the pathologic severity of gastroesophageal reflux and the development of Zenker diverticulae: it is thought that repeated

exposure of the proximal esophagus and pharynx to low pH refluxate results in cricopharyngeal spasm and loss of normal coordination.

Symptoms of a cricopharyngeal diverticulum include dysphagia, halitosis, throat discomfort, a palpable mass, and regurgitation of undigested food. Some patients may suffer from recurrent aspiration pneumonia and in severe cases may develop lung abscesses.

The first diagnostic test should be a barium swallow [see Figure 5], which will delineate the size and position of the diverticulum. Initial assessment by endoscopic means is not recommended as there is a sizable risk of perforating the pouch with the endoscope.

Treatment is surgical and must include the division of the cricopharyngeus muscle. Smaller pouches may be treated by myotomy alone, whereas those larger than 2 cm should

Figure 5 Pharyngoesophageal diverticulum. A large Zenker diverticulum is shown in an elderly patient who presented with dysphagia, recurrent pneumonia, and regurgitation.

be excised.¹⁸ Endoscopic (transoral) approaches to diverticulectomy have also been described.¹⁹

Midesophageal diverticulae are not typically associated with dysphagia. These true diverticulae are formed by traction from extraesophageal inflammation, most often granulomatous disease in subcarinal lymph nodes. Midesophageal diverticulae are usually asymptomatic, and treatment is focused on the underlying inflammatory process.

Epiphrenic diverticulae arise in the distal esophagus. These pulsion-type diverticulae are associated with underlying esophageal dysmotility^{20,21} and are also occasionally an isolated finding [see Figure 6]. In the absence of symptoms, expectant management is appropriate. When dysphagia is present, surgical management is necessary. The surgical approach, understood to incorporate “triple therapy,” must include (1) excision of the diverticulum, (2) an esophageal myotomy, and (3) an antireflux procedure.^{22,23}

Secondary Motor Disorders

In secondary dysmotility syndromes, the esophageal symptoms are a manifestation of a generalized systemic process. The etiology is

Figure 6 Giant epiphrenic diverticulum. Barium swallow shows an epiphrenic diverticulum in an elderly female with progressive dysphagia and weight loss; cancer was initially suspected.

thought to be progressive neuropathy and subsequent fibrosis. Common diseases associated with secondary dysmotility include rheumatologic syndromes, such as scleroderma, and diabetes mellitus.

MECHANICAL OBSTRUCTION

Webs

A web is a thin mucosal fold that protrudes into the esophageal lumen. Congenital webs are rare and usually restricted to the pediatric population. These are located in the middle and lower thirds of the esophagus.⁷ Acquired webs are normally located in the postcricoid cervical esophagus and are mostly asymptomatic. Etiologies for acquired webs include iron deficiency anemias (Plummer-Vinson and Paterson-Kelly syndromes) and dermatologic diseases. Webs are twice as common in female patients.

Dysphagia occurs intermittently with solids, and when symptoms arise, the orifice of the web is found to be less than 1.3 cm. Diagnosis is by barium swallow, and treatment involves mechanical dilatation using Savary bougies or endoscopic balloons. Underlying anemias and dermatologic conditions should also undergo assessment and appropriate treatment.

Rings

Esophageal rings are typically located in the lower third of the esophagus. Two types are typically described: muscular rings and mucosal or Schatzki rings.

Muscular rings are rarely associated with dysphagia and are often found incidentally in children undergoing barium swallow for other reasons. Schatzki rings are located at the Z-line (squamocolumnar junction) and are almost always seen in patients with GERD [see Figure 7]; consequently, the upper surface of a Schatzki ring is covered by squamous epithelium, whereas the lower surface is covered by columnar epithelium. Associations with eosinophilic esophagitis and GERD have been proposed. Diagnosis and treatment are as for esophageal webs.

Peptic Stricture

Peptic stricture was previously found in up to 10% of patients with GERD and represents the end stage of reflux-associated ulcerative esophagitis [see Figure 8]. The incidence of peptic strictures has been drastically reduced with the increased use of effective antireflux medications, chiefly the proton-pump inhibitors (PPIs).

Symptoms are described as progressive in nature and involve initial solid food dysphagia, progressing to liquid dysphagia. A history of reflux symptoms will also be elicited.

Figure 7 Schatzki ring. Barium swallow demonstrates a ring in a middle-aged man with severe gastroesophageal reflux disease symptoms and recent-onset dysphagia.

Initial assessment is by barium swallow. Peptic strictures are short segment, circumferential, and located at the squamocolumnar junction. A high index of suspicion for concomitant Barrett esophagus or frank cancer at the site of

Figure 8 Severe ulcerative esophagitis. Shown is the appearance of severe ulcerative esophagitis, annular stricture, and evidence of esophageal shortening. The caliber of the narrowed segment suggests a benign etiology.

stricture must be kept. Treatment of isolated peptic strictures includes acid suppression and endoscopic dilatation. In the past, peptic strictures were usually an indication for surgical correction; however, recent clinical experience with careful repeated dilatations combined with effective acid suppression

Figure 9 Midesophageal squamous cell carcinoma. Shown is the classic appearance of a midesophageal squamous cell carcinoma. Mucosal irregularity is apparent within the lesion, along with proximal dilatation and shouldering at the upper and lower borders. Bronchoscopy confirmed anterior penetration of tumor into the airway mucosa.

Figure 10 Caustic ingestion. Barium swallow from a 22-year-old patient after ingestion of toilet cleaner showing a long, stringlike lumen spanning the midesophagus to the stomach. Dilatation was impossible, and esophageal resection with colonic interposition was performed.

therapy (using PPIs) has rendered surgical treatment an uncommon occurrence.

Cancer

Dysphagia is the presenting complaint in the majority of patients with esophageal cancer. The temporal course is usually short and rapidly progressive. Weight loss is a prominent feature. Locally advanced cancers causing airway fistulization may present with aspiration (swallow-cough sequence) [see Figure 9]. Evaluation and staging should proceed as per established guidelines.

ODYNOPHAGIC SYNDROMES

Caustic Ingestion

Caustic agents are found in many household cleaning products. Ingestion is typically accidental but may be related to a suicide attempt. The pH of the offending agent (less than 2 or greater than 12), the volume ingested, and the total contact time with the esophageal mucosa are the determinants of the severity of the esophageal injury.⁸ Immediate flexible endoscopy is required to assess the degree and severity of the injury.⁹ Frank perforation or instability mandates immediate surgical exploration and resection. Sites most commonly affected include the distal esophagus and stomach; there is relative sparing of the upper pharynx and esophagus because of rapid transit through these regions.

Injuries will mature into strictures, which require serial assessment by barium studies starting 4 weeks after the initial injury [see Figure 10]. Repeated dilatations are typically required, although these procedures are technically challenging and sometimes dangerous as a result of the intense fibrosis, which virtually obliterates the esophageal lumen. A large majority of these patients do not have satisfactory results with dilatation as a result of an inability to

Figure 11 Dysphagia and odynophagia secondary to tuberculous lymphadenitis in the neck and mediastinum arising in an immunocompromised patient with chronic HIV infection. (a) Computed tomography image showing extensive necrotizing inflammation in the mediastinal lymph nodes (long arrow), air within the esophagus (arrowhead), and a collection of extraluminal air in the mediastinum (short arrow). (b) Contrast swallow study using water-soluble contrast, showing extravasation of contrast into the mediastinum (arrowhead) and fistulization between the esophagus and the right bronchial tree (arrow). Esophagoscopy showed extensive destruction of the esophagus by the mediastinal infection and multiple small fistulae into the airway. A covered self-expanding esophageal stent was inserted to block the fistula, followed by aggressive antituberculous therapy. The fistula healed, and the patient continues to do well clinically.

establish an esophageal lumen or an inability to maintain an adequate lumen despite repeated dilatations. Resection and reconstruction using colonic interposition become necessary.

Eosinophilic Esophagitis

This rare inflammatory condition is characterized by eosinophilic infiltrates isolated to the esophagus.²⁴ Intermittent dysphagia to solid food and pain are commonly noted, and associated manometric abnormalities (hypercontractility) are found in up to 60% of patients. Barium studies and endoscopy are often normal in appearance. Glucocorticoids and leukotriene antagonists represent currently accepted treatment.⁷

Infections

Infectious causes of dysphagia associated with odynophagia include intrinsic infections such as esophageal candidiasis, herpetic infections, and cytomegaloviral illness. Treatment is

based on the infectious agent involved. Rarely, extrinsic infection of the esophagus (originating in neighboring necrotizing mediastinal lymph nodes) can occur, causing dysphagia, odynophagia, and other potentially disastrous complications [see Figure 11].

Conclusion

Evaluation of the patient presenting with dysphagia represents a challenge for the surgeon. A careful history is key in determining likely etiologies. The barium swallow should be the first diagnostic test to be considered, with endoscopy to follow. Esophageal manometry represents the gold standard for diagnosing benign, functional (motor) disorders. Treatment is varied and depends on the etiology of the dysphagia.

2 COUGH AND HEMOPTYSIS

Shahriyour Andaz, MD, FACS, FRCS, and Svetlana Danovich, DO, PhD

Cough is one of the most common symptoms in patients seeking medical attention from the office-based physician.¹ In the United States, it accounts for approximately 30 to 50 million physician visits each year, and more than \$1 billion is spent annually on its workup and treatment.² Despite its massive burden on health care resources, cough is often dismissed as an unimportant irritation rather than a symptom of major socioeconomic importance.³ Hemoptysis, however, may not be as common a presenting complaint, and even mild hemoptysis is distressing to many patients and physicians and calls for prompt attention and diagnosis. It may range in severity from mild blood streaking in sputum to massive hemorrhage that, if left untreated, can lead to shock and rapid death from blood loss and asphyxiation. Every case of hemoptysis warrants a thorough clinical evaluation. Cough and hemoptysis can result from a wide variety of conditions, ranging from fairly non-life-threatening causes (e.g., bronchitis) to life-threatening ones (e.g., lung cancer). Because both cough and hemoptysis may be signs of urgent or life-threatening disease, patients who present with either or both of these symptoms should undergo a thorough, methodical workup consisting of a detailed history, a careful physical examination, and appropriate diagnostic studies.

Cough

DEFINITION

Cough is a forceful release of air from the lungs that can be heard. Coughing protects the respiratory system by clearing it of irritants and secretions. Although people can cough voluntarily, a cough is usually a reflex triggered when an irritant stimulates one or more of the cough receptors found at different points in the respiratory system.

Cough is a reflex defense mechanism that consists of an acute rapid inspiratory phase followed by an equally rapid and forceful expiratory phase against a closed glottis. Rapid opening of the glottis and brisk forceful expulsion result in the clearance of inhaled pathogens, aeroallergens, irritants, particulate matter, secretions, and aspirate.⁴ Impaired cough reflexes significantly increase the risk of pulmonary infection from retained secretions. Cough helps maintain airway function and lung capacity for gas exchange.^{5,6}

The cough reflex is initiated by the irritation of cough receptors that exist not only in the epithelium of the upper and lower respiratory tract but also in the pericardium, lower esophagus, stomach, and diaphragm.^{7,8} These receptors can be triggered by chemical and mechanical stimuli such as foreign bodies, irritant particles, fumes, and extrinsic pressure from masses (e.g., lung cancer), edema from pulmonary parenchymal infection (e.g., pneumonia or abscess), or pulmonary parenchymal fibrosis resulting from any of a variety

of interstitial lung diseases (e.g., idiopathic pulmonary fibrosis or sarcoidosis).

The airway sensory receptors are either primarily mechanically sensitive (low-threshold mechanoreceptors) or primarily chemically sensitive (chemosensors or, alternatively, nociceptors). Mechanoreceptors are of two types: rapidly adapting receptors (RARs) and slowly adapting receptors (SARs). They are sensitive to many mechanical stimuli, including changes in lung volume, airway smooth muscle constriction, and airway wall edema. As their names suggest, RARs display rapid adaptation (i.e., a rapid reduction in the number of action potentials) during sustained lung inflations, whereas SARs adapt slowly to this stimulus. RARs and SARs have different mechanical activation profiles. Thus, RARs may be activated during both inflation and deflation of the lungs (including lung collapse). SARs, on the other hand, display activity during tidal inspirations, peaking just prior to the initiation of expiration. Even though the RARs and SARs are not chemosensitive, they do get activated secondary to airway smooth muscle contraction, mucous secretion, or edema formation caused by bradykinin and capsaicin.

Chemically sensitive airway afferent fibers become recruited during airway inflammation or irritation. They are typically activated by a wide range of chemicals, including capsaicin, bradykinin, adenosine, and prostaglandin E₂. Chemosensors are stereotypically defined by their responsiveness to the irritant chemical capsaicin and, hence, the expression of the capsaicin receptor. The transient receptor potential cation channel, subfamily V, member 1 (TRPV1), also known as the capsaicin receptor, is a protein that, in humans, is encoded by the *TRPV1* gene. This protein is a member of the TRPV group of the transient receptor potential family of ion channels. TRPV1 is a nonselective cation channel that may be activated by a wide variety of exogenous and endogenous physical and chemical stimuli. The best known activators of TRPV1 are heat greater than 43°C and capsaicin, the pungent compound in hot chili peppers. Airway chemosensors are sometimes thought of as high-threshold mechanosensors. Within this group are fibers that are not readily excited by mechanical stimulation (e.g., bronchoconstriction, lung inflations, light touch) but can be activated using severe mechanical manipulations (e.g., lung hyperinflation, forceful punctate stimuli) and one or more chemical stimuli (e.g., capsaicin, bradykinin, adenosine).^{9–12}

Afferent fibers from cough receptors in the airways converge via the vagus nerve on brainstem sites in the nucleus tractus solitarius. The nucleus tractus solitarius is connected to respiratory-related neurons in the central respiratory generator that coordinate the efferent cough response.¹³ Sensation of the cough reflex can also arise in the brainstem neurons. Higher cortical centers can also voluntarily inhibit or produce cough.^{14,15}

CLINICAL EVALUATION

Guidelines from the American College of Chest Physicians distinguish three categories of cough based on duration:

- Acute cough, lasting less than 3 weeks
- Subacute cough, lasting between 3 and 8 weeks
- Chronic cough, lasting more than 8 weeks¹⁶

Cough can be the first indication of serious pulmonary or extrapulmonary pathologic conditions; the differential diagnosis of cough includes infectious, inflammatory, and neoplastic conditions and many pulmonary disorders [see Table 1]. The most common cause of acute, transient cough is the common cold. The most prevailing genesis in a series of 184 patients with subacute cough (lasting 3 to 8 weeks) was postinfectious cough (48%), postnasal drip (33%), and cough-variant asthma (16%).⁴ The most frequent etiology of chronic cough includes asthma, postnasal drip, sinusitis, chronic bronchitis, and reflux disease. The etiology of chronic cough can be multifactorial. For example, in a study of 88 consecutive unselected immunocompetent patients referred to pulmonary outpatient clinic for evaluation of chronic cough, 39% had a single cause of cough, 42% had two causes, and 17% had three causes. The most common causes of chronic cough were gastroesophageal reflux disease (GERD) (71.6%), postnasal drip syndrome (67%), asthma (23.9%), and bronchiectasis (8%). When considering only patients with cough for at least 3 weeks, who are nonsmokers and not on angiotensin-converting enzyme (ACE) inhibitors, with normal or nearly normal and stable chest radiographs, 99.4% will have GERD, postnasal drip syndrome, and/or asthma.¹⁷

Table 1 Differential Diagnosis of Cough

Acute infections
Acute bronchitis
Viral and bacterial pneumonias
Pertussis
Chronic infections
Bronchiectasis
Tuberculosis
Cystic fibrosis
Airway diseases
Asthma
Chronic postnasal drip
Chronic bronchitis

Emphysema
Chronic interstitial lung fibrosis
Sarcoidosis
Tumors
Primary lung carcinoma
Benign airway tumors
Mediastinal tumors
Cardiovascular diseases
Congestive heart failure
Pulmonary embolism
Other diseases
GERD
Recurrent aspiration
Endobronchial stents
Drugs
ACE inhibitors

ACE = angiotensin-converting enzyme; GERD = gastroesophageal reflux disease.

The cause of cough can be determined from a comprehensive history and physical examination. In fact, some studies estimated that the cause of cough is found in up to 80% of cases from the history and physical examination alone.^{17,18} The initial approach to the diagnosis of cough is a careful and detailed review of the history of the patient's cough, especially its features, including time of occurrence, frequency, duration, precipitating or aggravating factors, whether it is productive or nonproductive, and the color of the expectorant.¹⁹ In the study of 71 immunocompetent patients with chronic cough productive greater than 30 mL of sputum/day, all patients underwent careful evaluation, including chest radiography, and other tests being selectively administered, including sinus x-rays, allergy evaluation, pre- and post-bronchodilator spirometry, methacholine challenge, barium swallow, sputum culture, sputum cytology, fiberoptic bronchoscopy, and studies of cardiac function. A specific cause of chronic cough was determined in 97%: postnasal drainage syndrome (40%), asthma (24%), GERD (15%), acute and chronic bronchitis (11%), bronchiectasis (4%), and left ventricular failure (3%).⁴

MANAGEMENT

Acute Cough

Pneumonia (bacterial, viral, and aspiration) can present with fever, cough, and shortness of breath. Patients may also complain of pleuritic chest pain. Diagnosis is often made on a chest x-ray, sputum, and blood cultures, and treatment is directed toward the causative organism.

Asthmatic patients can develop cough in response to various provoking factors (allergens, cold, and exercise) and may not always be associated with airflow obstruction, wheezing, or dyspnea. The cough is often nocturnal, and the diagnosis is supported by bronchial hyperresponsiveness using a bronchial challenge test using nebulized methacholine or histamine and spirometry flow rates.²⁰ Cough can be the first sign of worsening of asthma; physicians should look for a fall in early-morning peak flows [see Figure 1].

Chronic Cough

Chronic bronchitis Chronic bronchitis accounts for about 10% of cases of chronic cough.²¹ The typical patient is a smoker experiencing productive cough. There is a wide spectrum of the disease, from mild early-morning sputum production to a chronic variety in patients with severe disabling chronic obstructive airway diseases.^{22–28} In a smoker, a chronic cough is not a particularly worrisome symptom; however, if the character of the cough or the quality of the sputum changes, further workup is indicated to look for a possible superimposed infection or neoplasm.²⁷ Any degree of hemoptysis in a former smoker should be taken seriously, especially if it is not associated with an infection. A chest x-ray may not be diagnostic, and evaluation with chest computed tomography (CT) and/or bronchoscopy may be indicated.^{27,28} Treatment consists of cessation of smoking, antibiotics, bronchodilators, and oral or inhaled steroids [see Figure 2].

Postnasal drip Postnasal drip, also known as upper airway cough syndrome, occurs when excessive mucus is produced by the nasal membrane. The excess mucus

Figure 1 Acute cough algorithm for the management of patients over 15 years of age with cough lasting less than 3 weeks. CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease.

accumulates in the back of the nose and trickles down the throat. It is characterized by a sensation of nasal secretions of a drip at the back of the throat, often accompanied by the frequent need to clear the throat, and is associated with nasal discharge or nasal stiffness. Nasal secretions irritate the larynx and trachea, leading to activation of the cough reflex arc.²⁹ Postnasal drip occurs during the day or night and may be worse at night. Generally, the diagnosis is made on the basis of the history and the symptom complex. The symptoms may be vague at times, and the diagnosis is confirmed only when the patient responds to empirical therapy. In recalcitrant cases, an otolaryngologic examination may be required to exclude sinus disorders. Physical examination may reveal nasal edema, mucopurulent secretions, and the typical cobblestone appearance of the posterior pharyngeal wall.²⁹ CT scanning of the sinuses may be required if the diagnosis is uncertain. Steroid nasal sprays, antihistamines, and nasal irrigations with saline are useful for ameliorating symptoms.

Medications Cough is a well-recognized complication of ACE inhibitor therapy.³⁰ ACE inhibitors are prescribed for the treatment of hypertension and heart failure; 2 to 33% of patients report a dry cough.³¹ The cough can arise within a few hours of taking the drug but can also become apparent after only a few weeks or months; it improves within days or weeks of withdrawal of the drug but can take longer to resolve completely. ACE inhibitor cough can be caused by the accumulation of bradykinin and prostaglandin, which directly sensitize cough receptors. Cough may also result from nonselective beta-blocker therapy or may develop as a consequence of idiosyncratic reactions to a variety of drugs and herbal remedies.

Reflux disease GERD is commonly implicated as a cause of chronic cough. In fact, it may be the only symptom in GERD.³² Typically, symptoms of acid reflux, other than cough, are heartburn, chest pain, a sour taste, and regurgitation. Reflux of gastric contents to the larynx can cause reflux laryngitis with thickening, redness, and edema of the posterior larynx.^{33–35} The diagnosis is difficult to make if the typical symptoms of reflux and heartburn are absent. As awareness of reflux-induced asthma and cough grows, more patients are being evaluated with barium studies and esophageal pH monitoring, which often provide the correct diagnosis when clinical evaluation cannot.

Tumors In smokers, a change in the nature of cough or hemoptysis should alert the physician to an underlying carcinoma.²⁷ There may be associated weight loss and weakness. Malignant central tumors tend to be squamous cell carcinoma or small cell cancers and can have associated mediastinal lymphadenopathy detected as hilar or mediastinal fullness on a chest x-ray and confirmed on CT scans. Carcinoid tumors, for the most part, tend to be central endobronchial lesions, causing obstruction to the lumen of the bronchus, and appear as smooth, round, fleshy, and highly vascular lesions on bronchoscopy. Not uncommonly, patients with a carcinoid tumor of the airway will have been treated with inhalers and steroids for years because of the presumptive diagnosis of asthma. Patients with malignant fistulas between the airway and the esophagus either from the cancers eroding the lumens or as a result of breakdown after radiotherapy present with copious secretions and foul breath. These patients usually have advanced disease and are best palliated with covered stents in the trachea and/or the esophagus.

Figure 2 Chronic cough algorithm for the management of patients over 15 years of age with cough lasting more than 8 weeks. ACE = angiotensin-converting enzyme; CT = computed tomographic.

Other conditions associated with cough Bronchiectasis cough is associated with extensive secretions from overproduction, together with reduced clearance, of airway secretions³⁶ The patient produces mucoid or mucopurulent sputum, sometimes accompanied by fever, hemoptysis, and weight loss.³⁶ Cough can be the only presenting symptom. Bronchiectasis can be associated with postnasal drip and rhinosinusitis, asthma, GERD, and chronic bronchitis.³⁷ Bronchiectasis can lead to clubbing of the fingers. Common pathogens cultured from sputum include *Haemophilus influenzae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*.³⁷ Patients with immotile cilia syndrome (Kartagener syndrome) will have other hallmarks of disease, such as situs inversus, sinusitis, and recurrent otitis.³⁸ Diagnosis is made by the delay (over 12 minutes) in the patient's ability to taste the saccharine placed on the anterior nares. Treatment is directed at the recurrent infections in the sinuses, ears, and chest.

A chronic cough may also be a consequence of congestive heart failure (CHF) (from any cause), although this is not a

common occurrence. Mild CHF with symptoms of orthopnea at night may be associated with coughing. The diagnosis is made on the basis of a history of orthopnea and associated cardiac risk factors or valvular disease, followed by cardiac echocardiography. Occasionally, the presence of a small unrecognized tracheobronchial foreign body can lead to chronic irritation of the bronchial epithelium and then to a persistent cough; this presentation is more common in children than in adults.³⁹ The diagnosis is usually made by performing bronchoscopy in a patient who is believed to be harboring a foreign body on the basis of chest imaging.

Eosinophilic bronchitis is a rare cause of chronic cough that may be suspected in patients with no other clearly explainable diagnosis.^{40,41} Patients typically have a history of atopy, and the diagnosis is made on the basis of clinical suspicion and the results of bronchial epithelial biopsy. Steroids are the mainstay of treatment. Chronic cough can be a prominent symptom of occupational exposure in glass workers exposed to low-molecular-weight irritants, hydrochloric acid, and organic oils.^{42,43}

In the occasional patient, a chronic cough may be of psychogenic origin. Such a cough classically occurs during the daytime and is absent when the patient is asleep. This is described as short and explosive and usually has been triggered by a precipitating upper respiratory tract infection that leads to a “sensation of a trickle in the throat” and has subsequently persisted. It can be socially disruptive. The mainstay of treatment is creating an awareness in the patient and encouraging voluntary suppression of the cough and attempts at increasing the time interval between coughs.^{44,45}

Hemoptysis

DEFINITION

Hemoptysis is defined as expectoration of blood originating from the lower airways (tracheobronchial or pulmonary parenchymal). Hemoptysis can be traces or massive, potentially resulting in asphyxia by flooding the airways. By definition, a loss of over 600 mL over 24 hours is considered massive. However, even as little as 150 mL of rapid blood loss in a patient with compromised pulmonary functions can be disastrous because the total dead space of the airway is 150 mL.

HISTORY

Hemoptysis dates back to 400 BC, when Hippocrates described hemoptysis in patients with advanced phthisis (Latin, from Greek, from *phthinein*, to waste away). Greek physicians recognized hemoptysis as being caused by underlying tuberculosis. In 1938, Eloesser suggested lobectomy for hemoptysis.⁴⁶ In 1941, Pitkin performed the first pneumonectomy in a patient with bronchiectasis,⁴⁷ and in 1973, Remy and colleagues reported the first case of bronchial arterial embolization.⁴⁸

SURGICAL ANATOMY

There are two major sources of independent arterial inflow to the lungs: an anatomically consistent pulmonary circuit with the inflow through the pulmonary artery and return via the pulmonary veins and a highly variable and complex bronchial arterial system originating from the arch of the aorta, intercostals, or other arterial branches that supply the esophagus, mediastinal lymph glands, and spinal artery.

A bronchial artery greater than 2 mm is considered pathologic, and the bronchial arteries play the dominant role in hemoptysis as these vessels are subjected to higher systemic pressures.⁴⁹ As a rule, the blood seen in the sputum is derived from either the pulmonary arteries or the bronchial arteries; only rarely does it come from the pulmonary veins.^{50–52} Although the bronchial arteries provide less blood flow than the pulmonary arteries do, they supply the bulk of the blood received by the airways and, accordingly, are the source of the blood in most cases of hemoptysis.

ETIOLOGY

Inflammatory processes, including bronchitis, bronchiectasis, tuberculosis, fungal infections, lung abscess, and cystic fibrosis, account for 60 to 70% of cases of hemoptysis, with tumors being responsible for 23%.^{53,54} In 7 to 34% of patients with hemoptysis, no identifiable cause can be found after careful evaluation.⁵⁵ Acute or chronic bronchitis leads to airway inflammation and is usually minor. Bronchiectasis

[see Figure 3] results in the destruction of the cartilage and is associated with proliferation of bronchial arteries in the smaller bronchi (third and fourth generation), resulting in massive hemoptysis.³⁶ Hemoptysis in tuberculosis results from the development of false aneurysms (Rasmussen aneurysm) of the bronchial or pulmonary artery as they traverse the walls of a tuberculous cavity or occasionally from a broncholith (calcified lymph gland) eroding through the bronchus. Broncholithiasis is also seen in histoplasmosis infections.

Various benign and malignant primary epithelial and soft tissue tumors have been associated with hemoptysis. The majority of primary airway tumors are malignant, with squamous cell carcinoma and adenoid cystic carcinoma being the primary malignancies most frequently seen in the trachea.^{56–62} In the case of primary lung cancers, massive hemorrhage is rare. Terminal bleeding in primary lung cancer is usually associated with a cavitary squamous cell cancer and involves major vessels adjacent to the main tracheobronchial airways.^{63,64} Endobronchial carcinoid tumors are highly vascular and appear as smooth, cherry red endobronchial tumors seen on bronchoscopy. Care must be taken when performing a biopsy of endobronchial tumors such as a carcinoid tumor as serious hemorrhage can result. Tumors arising from adjacent structures such as the esophagus and thyroid can erode the tracheobronchial tree, resulting in hemoptysis.

Trauma from penetrating injuries and iatrogenic injuries caused by the Swan-Ganz catheter and transbronchial biopsies can result in hemorrhage. Granulation tissue in a tracheobronchial stent placed for malignant tracheobronchial

Figure 3 Bronchial angiogram in bronchiectasis.

disease can bleed, requiring bronchoscopy and fulguration. Massive hemoptysis from a tracheostomy should alert the physician to the possibility of a tracheoinnominate fistula.

Mitral stenosis results in pulmonary congestion leading to hemoptysis. Other cardiovascular causes include pulmonary infarction, septic emboli,⁶³ and congenital diseases resulting in pulmonary hypertension, for example, Eisenmenger complex and primary pulmonary hypertension. Arteriovenous fistulas are a rare cause of massive hemoptysis.⁶⁵ Patients with Rendu-Osler-Weber syndrome may have telangiectasis of the skin or superficial mucous membranes.

DIAGNOSIS

History and Physical Examination

Taking a detailed history is essential to differentiate true hemoptysis from other sources of hemorrhage, such as the upper airways or blood being aspirated from the gastrointestinal (GI) tract. A history of coughing must be obtained. A history of spitting, epistaxis or nausea, vomiting, heartburn, and abdominal pain may differentiate other sources of the bleeding, that is, the upper airway or the GI tract. The physician must determine the duration and quantify the bleeding (e.g., a teaspoon, a cupful), the presence of clots, and other respiratory symptoms, such as shortness of breath, chronic cough, and chest pain. Direct observation is sometimes the best way to quantify the bleeding. Obtaining a history of previous cardiac or pulmonary diseases, smoking, and medications, including blood thinners such as aspirin, clopidogrel, or warfarin, is vital. Clinical evaluation may reveal clubbing in patients with chronic disease such as bronchiectasis, calf tenderness, or swelling in deep vein thrombosis, and the presence of telangiectasias, suggesting hereditary telangiectasia, may help narrow the differential diagnosis [see Table 2].

Investigations

Noninvasive investigations Routine chest x-rays are insensitive. Chest CT with contrast can often identify the cause of hemoptysis, especially for parenchymal lesions. CT scanners capable of three-dimensional helical reconstruction are especially useful in this regard. The coagulation profile should be determined and, if abnormal, corrected aggressively.

Table 2 Differential Diagnosis of Hemoptysis

Tracheobronchial disease
Acute or chronic bronchitis
Bronchiectasis
Neoplasms
Foreign bodies
Trauma
Tracheoinnominate fistula
Parenchymal disease
Infection
Interstitial lung disease
Pulmonary embolism
Pulmonary arteriovenous malformations
Miscellaneous conditions
Mitral valve disease
Coagulopathy

Endoscopy: diagnostic and therapeutic The key is to determine the side and site of bleeding, and bronchoscopy is particularly effective if performed within 48 hours of presentation.^{50–52} Bronchoscopy should preferably be carried out in a dedicated suite or the operating room by an experienced bronchoscopist with access to a variety of methods to arrest the hemorrhage using balloon catheters, endobronchial lasers, or endobronchial fulguration. Flexible bronchoscopy can be used for diagnostic purposes when the bleeding is minimal; however, in patients with massive hemoptysis, a rigid bronchoscope will allow not only rapid evacuation of active bleeding but also the use of other modalities to stop the hemorrhage. Selective ventilation with a double-lumen endotracheal tube may be used to temporize a critical situation.

Angiography: diagnostic and therapeutic Failure to identify the source of hemorrhage at bronchoscopy should prompt systematic bilateral angiography of the bronchial, nonbronchial, and pulmonary vascular bed. Direct evidence of extravasation of blood into the bronchi or the lung parenchyma occurs only during active hemorrhage. On occasion, the source of bleeding is a systemic vessel from the subclavian, intercostal, or phrenic vessels.⁶⁶ Most often, we rely on indirect evidence of the bleeding vessel, as suggested by vascular hypertrophy and tortuosity [see Figure 4], and aneurysm formation and collateral circulation [see Figure 5 and Figure 6]. Bleeding from the pulmonary vasculature resulting in hemoptysis is seen in less than 10% of patients with massive hemoptysis, especially in patients with arteriovenous malformations, lung abscess, and Rasmussen aneurysm seen in tuberculosis.⁶⁶ Bronchial arteriography and embolization should be considered in patients in whom resection is contraindicated [see Table 3]. Embolization can result in dramatic relief of hemorrhage. Unfortunately, the majority of patients with massive hemoptysis do not survive, dying of suffocation, and the goal of the treating physician should be to identify and treat these patients before they experience their final bleeding.

Figure 4 Bronchial arteriogram showing tortuosity.

Figure 5 Collateral circulation from the subclavian artery.

Figure 6 Collateral channels from phrenic artery.

MANAGEMENT

Medical

As with any potentially serious condition, evaluation of the “ABCs” (i.e., airway, breathing, and circulation) is the initial step. The overall goals of management of the patient with

Table 3 Contraindications to Surgical Resection

FEV ₁ < 40% of predicted
Unable to localize site at bronchoscopy
Unresectable cancer
Metastatic disease
Coagulopathy
Systemic disorder
Bilateral lung involvement

FEV₁ = forced expiratory volume in 1 second.

hemoptysis are threefold: aspiration prevention, bleeding cessation, and treatment of the underlying cause. Any patient with significant hemoptysis should be admitted to a monitored unit and evaluated promptly. Initial medical management consists of sedatives, cough suppressants, supplemental oxygen, and bed rest with dependent positioning of the pathologic side. Most cases of minor hemoptysis usually settle down with conservative measures. Patients with massive hemoptysis are, however, best monitored in intensive care units. Interventional techniques described earlier using bronchoscopy (flexible or rigid) and arteriography with embolization as required are used in stabilizing the patient.

Surgical

Surgery is best performed once the acute situation is under control and the site has been identified. There should be no medical contraindications, and the patient must have adequate pulmonary reserve. Pulmonary resection is the most effective method for controlling and preventing recurrent bleeding in most patients. Emergency surgery has a significantly higher morbidity and mortality than elective surgery. Surgical resection prior to hospital discharge must be considered in patients with massive hemoptysis even if the bleeding is stabilized as the recurrence rate is high (> 30%).⁶⁷ Surgical procedures depend on the pathology and pulmonary reserve. For benign disease and in patients with poor reserve, a limited resection may be appropriate, whereas in patients with malignant disease and with better pulmonary functions, a more radical approach with a lobectomy or even a pneumonectomy may be necessary.

SUMMARY

Hemoptysis must always be taken seriously. Death from massive hemoptysis occurs from asphyxiation. Every attempt must be made to localize the site of bleeding. Whenever possible, attempts must be made to control massive hemorrhage by interventional techniques. Elective resection has less morbidity and mortality than emergency surgery.

3 CHEST WALL MASS

Michael E. Friscia, MD, and John C. Kucharczuk, MD

Chest wall masses are relatively uncommon in clinical practice. Together they encompass a variety of different processes, which may be benign or malignant. Unfortunately, few surgeons have a working knowledge of the etiology, evaluation, treatment, and prognosis of patients with primary or secondary chest wall masses. Often unfamiliarity leads to inappropriate diagnostic studies, delays in treatment, and frustration for the patient and surgeon alike. The intent of this chapter is to review the clinical presentation and diagnostic procedures required to evaluate and treat a patient presenting with a chest wall mass. We begin with the formulation of a clinical algorithm to streamline the evaluation, diagnosis, and treatment of patients with chest wall masses and conclude with a review of the specific causes of chest wall masses.

The chest wall contains a number of distinct tissues, including skin, fat, muscle, bone, cartilage, lymphatics, blood vessels, and fascia. Each of these component tissues has the capability of producing either a benign or a malignant primary chest wall mass. The chest wall is also in intimate proximity to a number of organs, which may cause a mass by extension of a malignancy or infection. These include the breast, the lung, the mediastinum, and the pleura. Additionally, because of the large surface area of the chest wall, it can be the site of metastasis from distant malignancies, including carcinomas and sarcomas. The primary framework for classification of chest wall masses is shown in Table 1.

Clinical Evaluation

The initial evaluation of these patients begins with a careful history noting the symptoms associated with the mass and the history of its growth. A personal history of malignancy should raise concern for a metastatic lesion. A complete physical examination is performed to evaluate other sites of disease and delineate comorbid medical conditions that will impact the patient's candidacy for resection. Previous radiographs, if available, are reviewed to determine the rapidity of the growth. If the mass is palpable, its size and characteristics (hard versus soft, fixed versus mobile) are noted.

A computed tomographic (CT) scan of the chest is required if chest wall involvement of an intrathoracic lesion is suspected. For primary chest wall masses, magnetic resonance imaging (MRI) can be useful for further characterization. An MRI allows delineation of tissue planes and the relationships to major neurovascular structures.¹ Chest radiography is often performed initially but is of little use.

Table 1 Framework for Classification of Primary and Secondary Chest Wall Masses

Primary masses of the chest wall
Benign masses
Infectious masses
Soft tissue neoplasms
Bone and cartilage neoplasms
Malignant masses
Soft tissue malignant neoplasms
Bone and cartilage malignant neoplasms
Secondary masses of the chest wall
Tumor invasion from contiguous organs
Metastasis from distant organs

The next step is to decide whether to pursue a tissue diagnosis prior to proceeding with definitive therapy. For lesions less than 3 cm, whether suspected of being benign or malignant, excisional biopsy is performed for diagnosis and treatment. For lesions greater than 3 cm that can produce significant morbidity with resection, a preoperative tissue diagnosis is obtained.

Fine-needle aspirations (FNAs) are technically simple and can be performed in the office at the initial patient evaluation but are best used when metastasis is suspected. Lack of histology and tissue architecture severely limits the use of FNA in distinguishing benign from malignant primary chest wall tumors. In these cases, a core-needle biopsy or incisional biopsy is performed. Both techniques provide tissue for histology, and both must be performed so that the biopsy track will be completely excised at the time of definitive surgery. Given the easy access to most chest wall masses, many patients will tolerate a core-needle biopsy in the office, which can expedite the diagnostic process.²

Benign Primary Masses of the Chest Wall

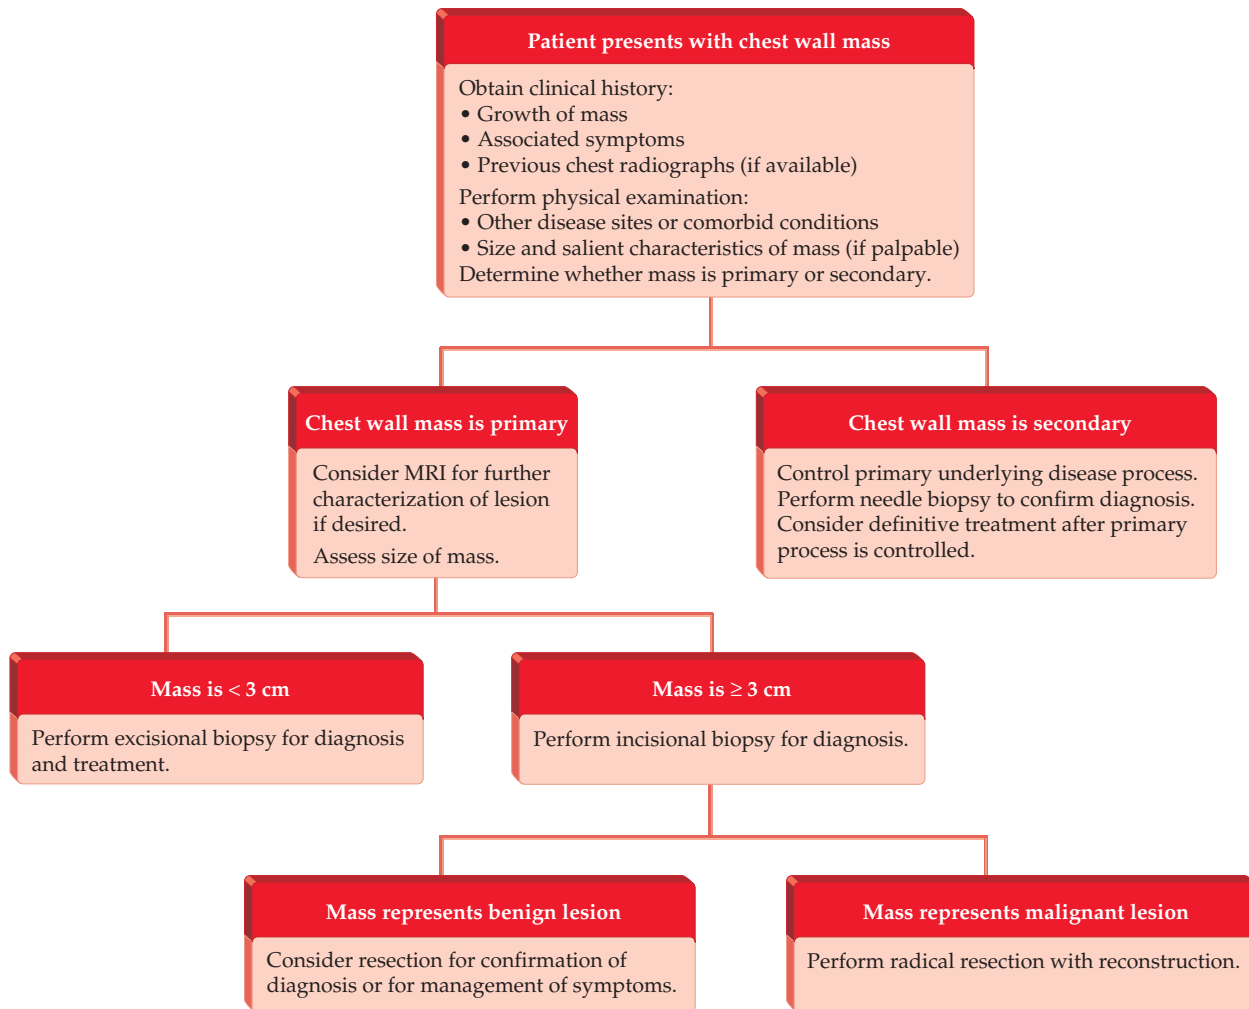

INFECTIOUS MASSES OF THE CHEST WALL

Sternal Infections

Primary sternal osteomyelitis is rare but may be seen in intravenous drug abusers. Much more common is osteomyelitis following median sternotomy. Approximately 1 to 3% of median sternotomies for cardiac surgery are complicated by sternal

Evaluation of Chest Wall Mass

wound infection.² The risk factors for this complication include diabetes, use of bilateral internal mammary arteries, and reoperation.³ These patients present with pain, drainage, and systemic signs of infection. Most of these infections have deep extension into the mediastinum as well as sternal osteomyelitis. When sternal osteomyelitis is suspected, a CT scan of the chest can help determine the extent of mediastinal soilage, but, generally, the patient is taken directly to the operating room for exploration and sternal débridement. Aggressive surgical débridement of the bone and cartilage with flap closure is associated with the best clinical outcomes.⁴

Special mention must be made of the patient who presents after sternotomy with a pulsating sternal mass. These patients have a pseudoaneurysm of the underlying aorta and are at risk for exsanguination. They should undergo an emergent CT angiogram or aortogram to confirm the diagnosis. They must then be taken directly to the operating room, where they are placed on cardiopulmonary bypass through femoral cannulation and are cooled to hypothermia prior to opening the sternum as repair may require circulatory arrest.

Sternoclavicular Joint Infections

Sternoclavicular joint infections present as painful palpable masses overlying the sternoclavicular joint, as shown in Figure 1. These infections are often associated with intravenous drug abuse, infected indwelling subclavian catheters, and trauma. The majority of patients have some underlying risk factor, including diabetes, hepatic or renal insufficiency, or a history of systemic sepsis. The diagnosis is made by a combination of history, physical examination, and MRI of the chest with attention to the sternoclavicular joint. The typical findings include a collection around the joint and abnormal signal intensity in the bone and cartilage [see Figure 2]. Treatment consists of wide resection of the sternoclavicular joint, including the proximal third of the clavicle as well as débridement of the manubrium.⁵ The proximal portion of the first or second ribs can be involved and also requires resection. Immediate reconstruction is performed by rotation of a pectoralis muscle flap into the resection cavity. Postoperatively, the patients are treated with 6 weeks of intravenous antibiotics. Most require intensive postoperative physical therapy to restore strength, function, and mobility in the upper extremity.

Figure 1 Sternoclavicular joint infections present as painful palpable masses overlying the joint.

Figure 2 A computed tomographic (CT) scan shows the typical appearance of sternoclavicular joint infection, including fluid collection around the joint and tissue stranding.

Osteomyelitis of the Rib

Osteomyelitis of a rib presents as a painful, swollen mass overlying an infected segment of rib. Often a draining sinus tract is present. The diagnosis is made on a clinical basis. A CT scan of the chest is obtained to rule out underlying intrathoracic pathology such as an empyema. Treatment is resection of the infected bone with soft tissue coverage of the defect. Care is taken to avoid contamination of the underlying pleural cavity during rib resection. In children, the diagnosis can be facilitated by the use of ultrasonography, which demonstrates obliteration of the intermuscular planes adjacent to the infected rib and pericostal edema.⁶ As with adults, the range of pathologic organisms recovered can be quite wide.

BENIGN NEOPLASMS OF THE CHEST WALL

The benign neoplasms of the chest wall are shown in Table 2.

Benign soft tissue neoplasms of the chest wall usually present as slowly growing, painless masses. Often plain radiographs and a CT scan of the chest are obtained, although they are not always necessary.

On examination, benign soft tissue lesions are usually soft and mobile. The CT scan shows a homogeneous mass without necrosis, infiltration of associated soft tissue, or destruction of associated bone. Small (< 3 cm) soft tissue lesions are completely removed by excisional biopsy for definitive diagnosis and treatment. Larger lesions (> 3 cm) are approached with a core-needle biopsy first to rule out a malignant soft tissue neoplasm. If the lesion is confirmed to be benign, it is resected with close negative margins to minimize the size of the surgical defect. If it is determined to be malignant, an aggressive wide excision is performed with immediate reconstruction.

Desmoid tumors deserve special mention in that they are borderline neoplasms.⁷ These tumors generally arise in the muscle and fascia around the shoulder. Although they appear histologically benign, they can infiltrate adjacent structures and have a high tendency for local recurrence, which can make surgical treatment for recurrence morbid and disfiguring. For these reasons, desmoid tumors are best treated with radical surgical excision. The largest current series demonstrates that a positive surgical margin is associated with an 89% recurrence rate, whereas with a negative margin, recurrence is less than 20%.⁸

Benign Bone and Cartilage Neoplasms

Osteochondroma is a benign cartilaginous neoplasm that can occur in any bone that undergoes enchondral bone formation. Essentially, these tumors are hamartomas of the growth plate. The knee is the most common site of occurrence. In the

Table 2 Benign Neoplasms of the Chest Wall by Site of Origin

Eosinophilic granuloma

chest, they arise in the metaphyseal regions of the anterior ribs. Most are asymptomatic and found on a screening chest radiograph where an eccentric growth pattern is noted at the costochondral junction. The diagnosis is made from a characteristic pattern of stippled calcification within the tumor on plain x-ray. In children, they are followed unless causing pain or increasing in size; in postpubescent and adult patients, they are resected to confirm the diagnosis and rule out malignancy.

Chondromas are the next most common benign neoplasm of the chest wall. They occur along the costochondral junctions between the anterior ribs and the sternum. Unfortunately, the distinction between chondroma and chondrosarcoma cannot be made on clinical or radiographic grounds; therefore, excision is required for diagnosis. This results in a significant surgical defect, which usually requires complex reconstruction, including prosthetic material to provide rigid structure and soft tissue coverage.

Fibrous dysplasia is a benign cystic lesion of the medullary cavity of the rib that usually presents as a painless lesion incidentally found on a screening chest x-ray. Medullary replacement by fibrous tissue creates a radiolucent appearance on an x-ray. These lesions are treated conservatively and simply followed. Local resection is indicated if pain develops or the lesion enlarges on serial x-rays.

Malignant Primary Masses of the Chest Wall

Malignant soft tissue lesions of the chest wall constitute a large number of diverse pathologies. The primary malignant masses of the chest wall are listed in Table 3.

SOFT TISSUE

Sarcomas are the most common primary malignant neoplasm of the chest wall. On examination, sarcomas of the chest wall can be quite sizable, as shown in Figure 3. They are painless in half of the patients. The clinical finding is a hard, fixed mass. No calcifications are visible on a CT scan of the chest, but bony invasion is common. The treatment is wide surgical excision. Gordon and colleagues reported the largest surgical series of patients with soft tissue sarcomas of the chest wall in 1991.⁹ The study included 149 patients who had undergone resection at the Memorial Sloan-Kettering Cancer Center in New York. The 5-year survival rate was 66%. Unfortunately, the study also included 32 patients who had desmoid tumors, which are not histologically classified as sarcomas or as malignant. A large retrospective study containing 55 surgically treated patients with soft tissue sarcomas of the chest wall was reported from a single institution in Brazil in 2005.¹⁰ In this series, fibrosarcoma accounted for nearly 53% of the cases. With wide surgical resection, the authors reported disease-free survival rates of 75% at 5 years and 64% at 10 years. The histologic grade of the tumor and the type of surgical resection were found to be independent

prognostic factors for disease-free survival. This is consistent with other studies that suggest that age, gender, symptoms, and size do not significantly impact survival.¹¹ The French Sarcoma Group published its retrospective series of soft tissue sarcomas of the trunk wall in 2009, which included 283 patients with chest wall sarcomas treated primarily with surgery.¹² Overall survival at 5 and 10 years was 57% and 52%, respectively. Interestingly, 22% of patients in this study had a previous history of radiation therapy, which adversely affected survival. Currently, no good data are available to recommend neoadjuvant treatment, which has become routine in the treatment of soft tissue sarcomas of the extremities. A single-institution, multidisciplinary experience with primary chest wall sarcomas was reported from The University of Texas M.D. Anderson Cancer Center in 2001.¹³ The retrospective review included patients with sarcomas of soft tissue, cartilage, and bone origin, as well as desmoid tumors. The cumulative 5-year survival was 64%, which is to be expected from surgery alone.

CARTILAGE AND BONE

Solitary plasmacytoma represents an uncommon chest wall mass caused by a localized collection of monoclonal plasma cells. Histologically, the plasma cells are identical to those seen in patients with multiple myeloma; however, unlike patients with multiple myeloma, they are confined to a single site. Patients generally present with pain and often have pathologic rib fractures. With soft tissue involvement, a palpable mass becomes evident. Tissue is required to make the diagnosis either by FNA, core-needle, or small incisional biopsy. The specimen should be sent for flow cytometry, which confirms the clonal nature of the cells.¹⁴ Definitive local radiotherapy is the treatment of choice for solitary bone plasmacytoma.¹⁵ Although local control is achieved in over 90% of patients with radiation alone, about 50% of patient progress to multiple myeloma within 2 years and require systemic treatment.¹⁶

Chondrosarcoma is the most common primary malignant tumor of the chest wall. Chondrosarcomas are found along the anterior sternal border or the costochondral arches and are more common in males than in females. The primary symptom leading to evaluation is pain. The best imaging modality is CT; however, there are no distinguishing radiographic characteristics to provide a definitive diagnosis, and core or incisional biopsy is required.¹⁷ Complete surgical resection with adequate surgical margins and immediate reconstruction is the treatment of choice. The Scandinavian Sarcoma Group published the largest series of patients with chest wall chondrosarcoma.¹⁸ Ninety-seven patients were treated with surgery; wide excision was associated with a 92% 10-year survival and a 4% local recurrence rate, compared with a 47% 10-year survival and a 73% local recurrence rate when margins were positive.

Ewing sarcoma is an aggressive primary malignant bone tumor that presents in children and adolescents with a painful, enlarging mass often associated with fever and malaise. Ewing sarcoma was initially distinguished from osteosarcoma because of its sensitivity to radiation. Although the cellular origin of Ewing sarcoma remains unclear, there appears to be a spectrum of tumors that share the same genetic translocation and are referred to as the Ewing family of tumors.¹⁹ The initial role of surgery in primary chest wall Ewing sarcoma is to obtain tissue for diagnosis. With smaller rib lesions, this may be in the form of an excisional biopsy. Therapeutically, these tumors are best approached with multimodality treatment, including preoperative chemotherapy followed by complete resection of residual disease.²⁰ A review of three multi-institutional trials from the Pediatric Oncology Group in 2003 suggested that the likelihood of a complete resection is improved with neoadjuvant chemotherapy followed by wide resection in patients with Ewing sarcoma and closely related primitive neuroectodermal tumors of the chest wall.²¹ If the resection is complete and the pathologic margins are negative, no radiation therapy is given. The avoidance of radiation therapy may be particularly important in children and adolescents because of the risk (10 to 30%) of developing a radiation-induced malignancy over their lifetime.²² Askin tumors are a small round cell tumor of the thoracopulmonary region and are members of the Ewing family of tumors. They are best managed by diagnostic biopsy and

preoperative chemotherapy followed by complete surgical resection.²³

Synovial sarcomas are rare but may arise on the trunk, where they present as a palpable chest wall mass. Despite the name, these lesions do not arise from synovial cells or joint cavities. They were originally named based on the appearance under light microscopy; however, these tumors are now known to arise from pluripotential mesenchymal cells.²⁴ The most important prognostic factor is tumor size.²⁵ Limited data suggest that although there may be an objective response to neoadjuvant chemotherapy, there is no detectable benefit on survival.²⁶ The current recommendation is aggressive surgical resection. Patients with very large tumors or positive surgical margins receive postoperative adjuvant treatment.

Secondary Masses of the Chest Wall

Secondary chest wall masses arise as direct extensions of a malignancy from a contiguous organ. Breast and lung cancer are the most common. The initial evaluation centers on staging the underlying disease. For example, a patient with a chest wall mass attributable to direct invasion of a primary lung cancer should undergo a staging workup to determine the extent of disease. If the patient is deemed an appropriate candidate for resection and is medically operable, he or she should undergo pulmonary resection with en bloc chest wall resection.²⁷ Following resection, the patient should be referred for adjuvant chemotherapy. The intent is cure, and the outcomes are stage specific.

Unfortunately, most women presenting with a chest wall mass from breast cancer have a local recurrence. Resection with reconstruction can be performed in this situation, but the benefit remains unclear. The Memorial Sloan-Kettering Cancer Center reported on 38 women who underwent extensive chest wall resection for recurrent breast cancer with a 0% operative mortality rate, but the 5-year survival rate was only 18%, and by 5 years, 87% of the patients had local recurrence.²⁸ Currently, chest wall resection of locally recurrent breast cancer must be considered on a case-by-case basis.

A large necrotic ulcer of the chest wall presenting after radiation therapy to the chest wall for previous malignancy should raise the suspicion for osteoradionecrosis. This is a locally destructive lesion characterized by infection and necrosis. The first step is to perform biopsies of the area to ensure that the lesion does not represent tumor recurrence. The preferred treatment is wide excision to healthy tissue and local or free flap coverage of the soft tissue defect, avoiding the use of prosthetic material whenever possible. Close collaboration with a plastic and reconstructive surgeon is critical to operative planning and success.²⁹

Conclusions

Chest wall masses are relatively unusual in clinical practice. Most surgeons have limited experience in diagnosis and

treatment. In general, it is important to move quickly to establish a tissue diagnosis as a physical examination and a radiographic study often cannot distinguish a benign from a malignant chest wall mass. The very unusual tumors will often require consultation with a highly specialized patholo-

gist to make the diagnosis and an oncologist to assist in treatment planning to optimize patient outcome.

Financial Disclosures: None reported.

4 PLEURAL EFFUSION

Michael A. Maddaus, MD, FACS, and Rafael S. Andrade, MD, FACS

Approach to the Patient with a Pleural Effusion

Pleural effusion is a common problem in surgical practice. It results from perturbations of normal pleural fluid transport, which are produced by three main mechanisms: abnormalities in Starling equilibrium, increased capillary and mesothelial permeability, and interference with lymphatic drainage. These mechanisms are associated with a variety of different causes [see Table 1].^{1,2} Often more than one mechanism is involved. An inflammatory effusion, for instance, is marked by increases in capillary and mesothelial permeability, which lead to elevated intrapleural oncotic pressure.

Pleural effusion is classified as either transudative or exudative, depending on the chemical composition of the fluid. A transudate is an ultrafiltrate of serum and has a low total protein content (≤ 3 g/dL); an exudate is the result of increased permeability and has a high total protein content. Increased pleural permeability results from complex inflammatory mediator interactions between the mesothelium (whose cells play an active role in inflammation, phagocytosis, leukocyte migration, tissue repair, antigen presentation, coagulation, and fibrinolysis^{3,4}) and the capillary endothelium. The distinction between transudative and exudative pleural effusion is clinically significant in that the two types of effusion have different causes [see Table 2].^{1,4}

Table 1 Pathophysiologic Mechanisms of Pleural Effusion

Mechanism	Specific Alteration	Cause
Abnormality in Starling equilibrium	Increased capillary and lymphatic hydrostatic pressure	Increased venous pressure (e.g., biventricular heart failure, renal failure)
	Decreased capillary oncotic pressure	Hypoproteinemia (e.g., nephrotic syndrome)
	Decreased intrapleural hydrostatic pressure	Ex vacuo effusion (e.g., atelectasis)
	Increased intrapleural oncotic pressure	Inflammation (e.g., infection, cancer, autoimmune disease)
Increase in capillary and mesothelial permeability	Increased filtration	Inflammation (e.g., infection, cancer, autoimmune disease)
Interference with lymphatic drainage	Obstruction	Cancer, structural abnormalities

Table 2 Causes of Transudative and Exudative Pleural Effusion

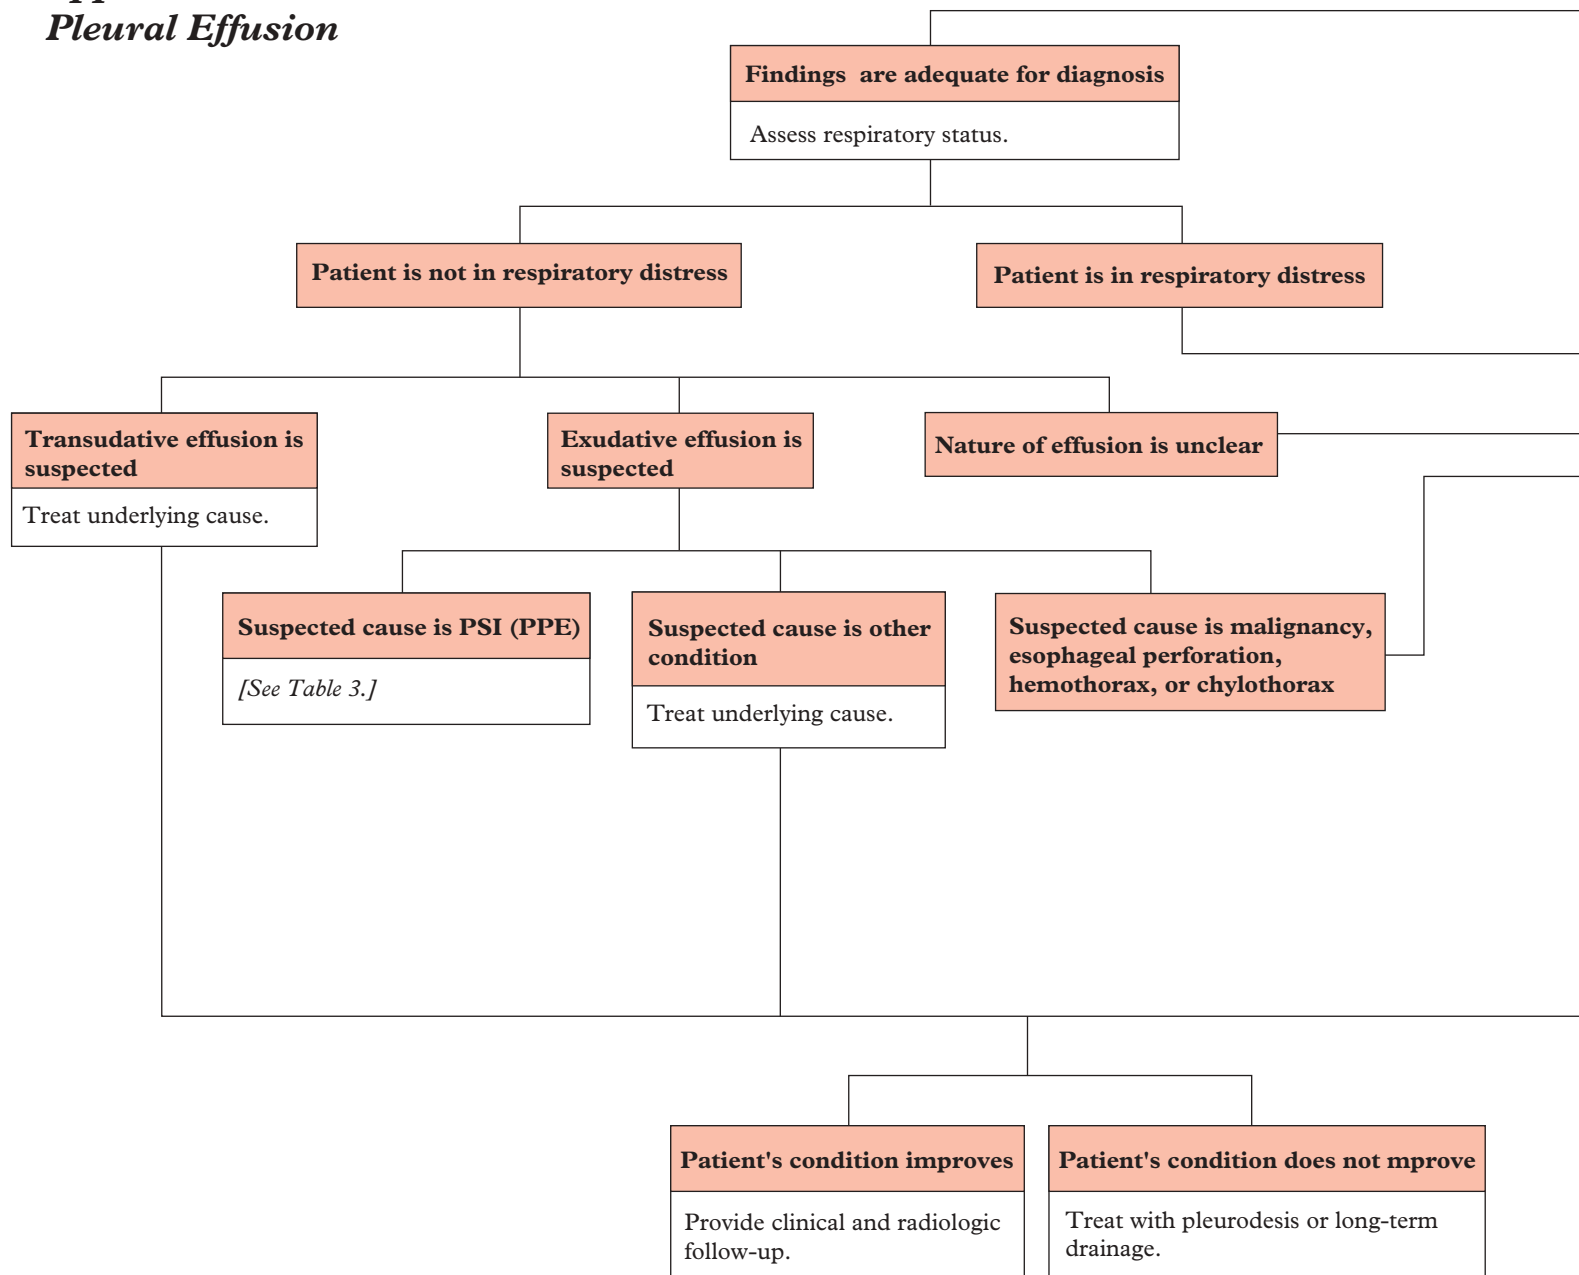

Type of Effusion	Cause
Transudative	Congestive heart failure Cirrhosis Nephrotic syndrome Acute atelectasis Renal failure Peritoneal dialysis Postoperative state Myxedema Postpartum state
Exudative	Pneumonia Malignancy Infection Esophageal perforation Hemothorax Chylothorax Pseudochylothorax Connective tissue diseases Drug-induced pleuritis Pancreatitis Uremia Postmyocardial infarction (Dressler syndrome) Chronic atelectasis Radiation therapy Asbestos exposure Meigs syndrome Ovarian hyperstimulation
Transudative or exudative	Pulmonary embolus

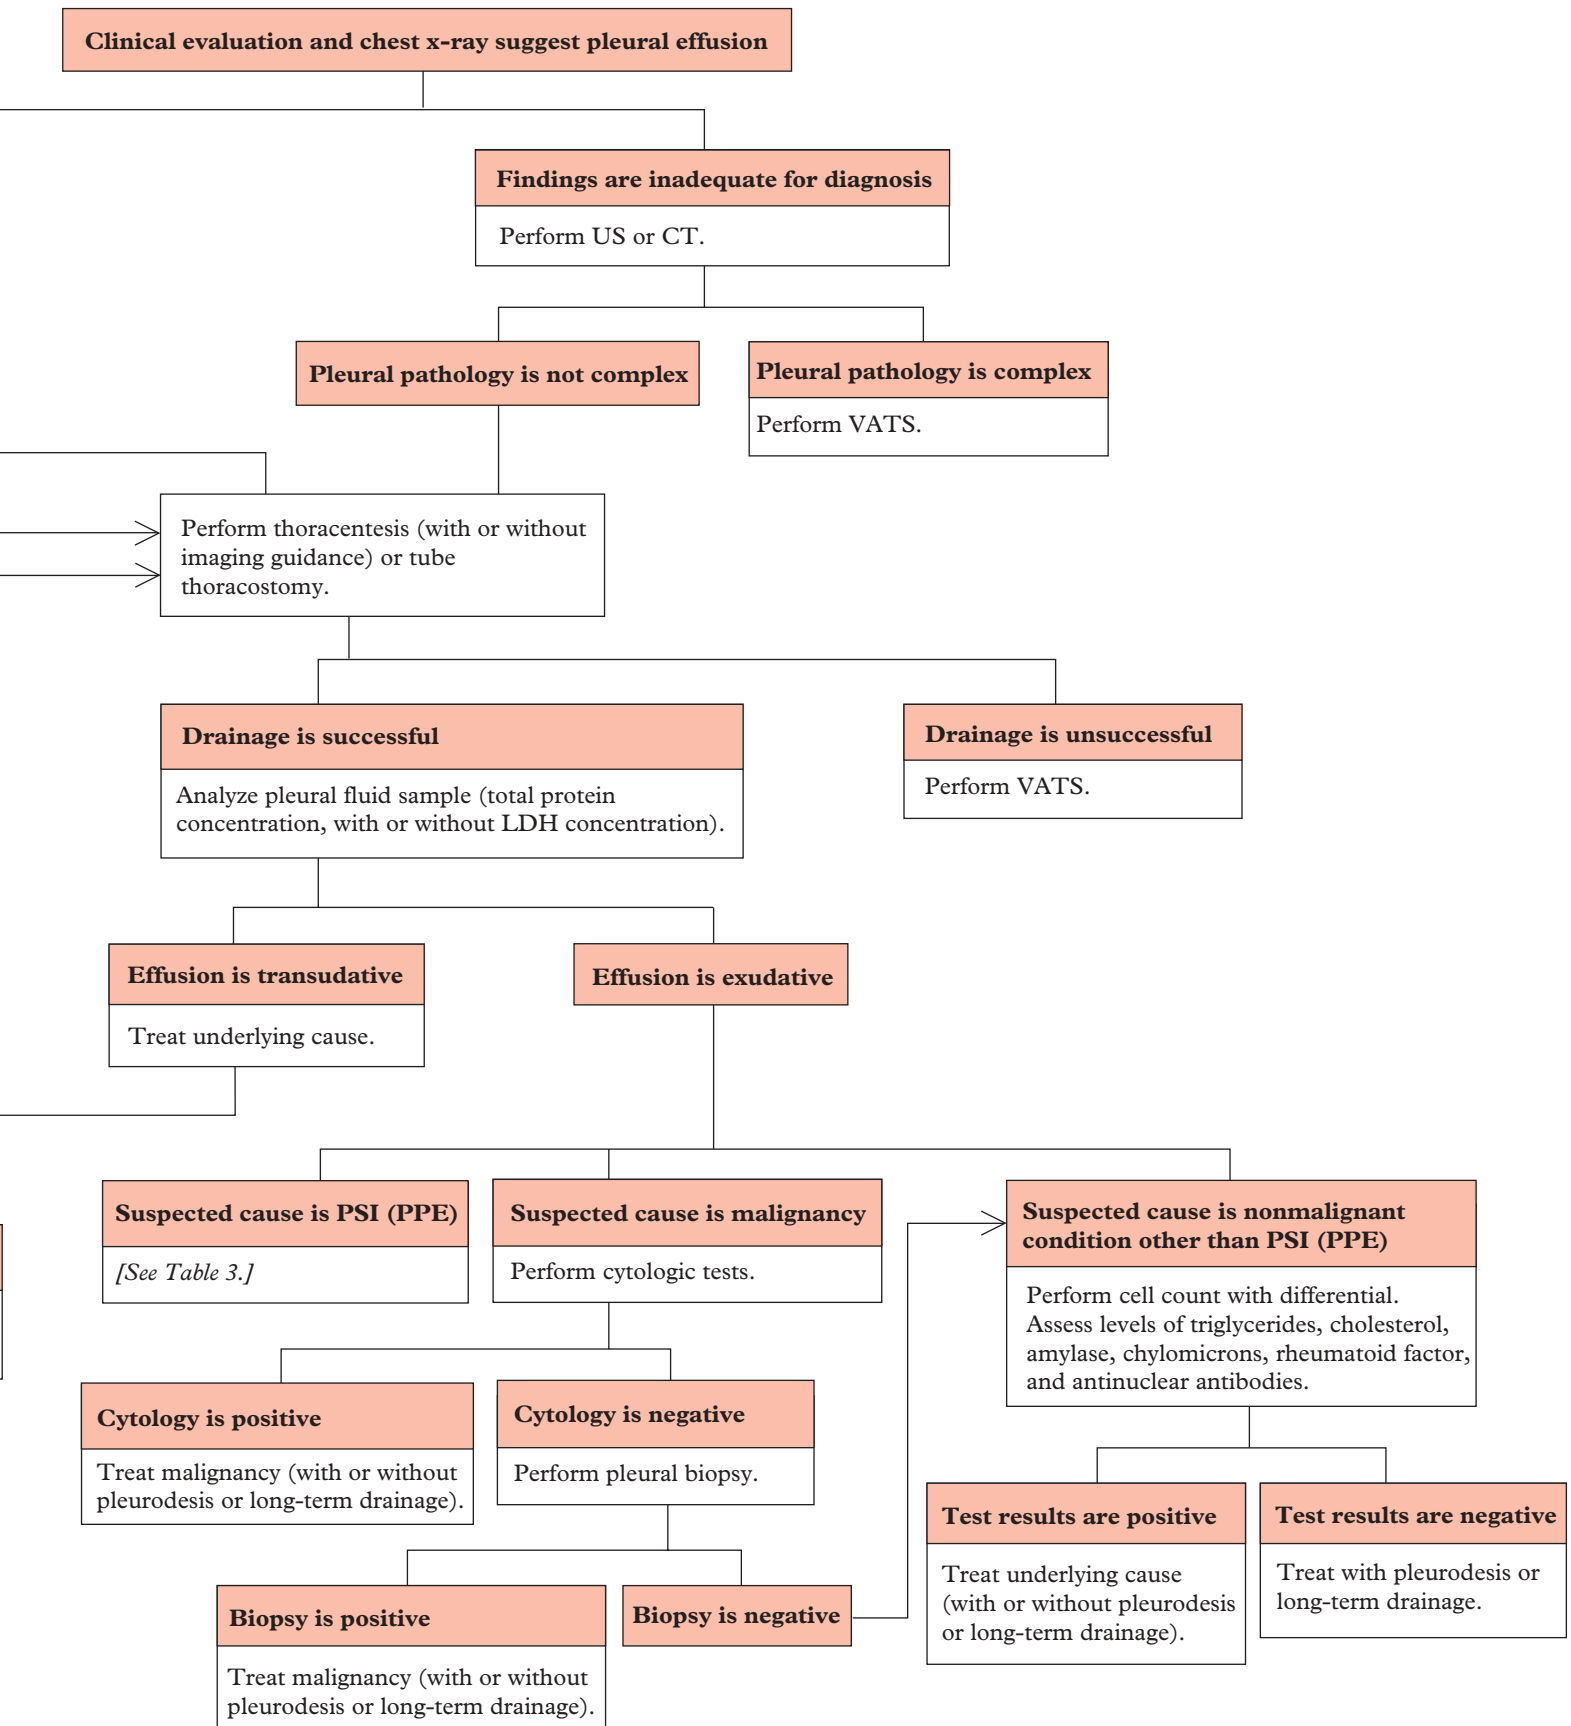

Clinical Evaluation

A complete history, physical examination, and clinical acuity are the initial tools used for diagnosing pleural effusion. Important facts from a patient's history (e.g., respiratory symptoms, pain, extrathoracic symptoms, duration of symptoms, previous medical conditions, and risk factors for cardiopulmonary diseases or cancer) can raise the index of suspicion for an effusion and provide guidance regarding possible causes. Careful physical examination of the chest can detect an effusion, and many physical signs may provide clues to the cause. Physical signs that are particularly useful for diagnostic purposes include jugular venous distention and tachycardia (suggestive of congestive heart failure); lymphadenopathy, digital clubbing, and localized bone tenderness (suggestive of lung cancer); and ascites (suggestive of ovarian tumors or cirrhosis).

Approach to the Patient with a Pleural Effusion

Pleural effusion can occur in a wide variety of clinical situations, however, and it often evades clinical detection by history and physical examination. Consequently, imaging tests are indispensable in the workup of a patient with a possible pleural effusion. Pleural fluid analysis, pleural biopsy, and thoracoscopy may also be required for evaluation.

Investigative Studies

IMAGING

Chest Radiography

To be detectable on a standard upright posteroanterior chest radiograph, an effusion must have a volume greater than 150 mL. If the volume is 150 to 500 mL, the lateral costophrenic angle will be blunted; if the volume is greater than 500 mL, a meniscus will be created.^{5,6} A lateral decubitus chest radiograph can detect minute effusions (< 50 mL), and as a general rule, a layering effusion that is at least 1 cm thick is accessible to thoracentesis.^{6,7} A loculated effusion may appear as a so-called pseudotumor on a chest radiograph and typically will not layer freely on a lateral decubitus radiograph. Subtle changes on an upright chest radiograph (e.g., accentuation of a fissure, elevation of a hemidiaphragm or increased separation between the lung and subdiaphragmatic gas [see Figure 1]) may also signal an effusion. Additional findings on a standard chest radiograph (e.g., laterality, the size of the cardiac silhouette, the position of the mediastinum, pulmonary parenchymal changes, pleural calcifications, and osseous abnormalities) may point to a specific cause.

Figure 1 Posteroanterior chest radiograph of a patient with bilateral pleural effusion reveals increased separation between the left lung and subdiaphragmatic gas (arrows).

Supine chest radiographs are less sensitive than other chest radiographs. With these images, suspicion of an effusion is triggered by increased homogeneous density of the lower hemithorax, loss of normal diaphragmatic silhouette, blunting of the lateral costophrenic angle, or apical capping [see Figure 2].⁸

Ultrasonography

Chest ultrasonograms are more reliable for detecting and localizing small (5 to 100 mL) or loculated pleural effusions than chest radiographs are.^{5,9,10} Ultrasonography is particularly helpful for guiding thoracentesis for small-volume effusions and for assessing pleural effusions in critically ill patients.^{6,11}

Computed Tomography of Chest

Computed tomography (CT) of the chest is a very sensitive tool for evaluating pleural effusion. Free-flowing fluid causes a sickle-shaped opacity in the most dependent portion of the thorax, and even small effusions are readily detected [see Figure 3]. CT may also reveal clues to the cause of the effusion, such as a fluid-fluid level (suggestive of acute hemorrhage), pleural thickening and enhancement (suggestive of pleural space infection [PSI] [see Figure 4]), calcified pleural plaques (suggestive of asbestosis), and diffuse irregular nodularity and pleural thickening (suggestive of pleural metastases or mesothelioma). CT is especially useful for characterizing loculated effusions, for differentiating pleural thickening or pleural masses from pleural effusion, for distinguishing between effusion and lung abscess, and for guiding and monitoring closed drainage of effusions.^{6,10,12,13}

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the chest provides no useful information beyond what can be obtained with CT.

Figure 2 Supine chest radiograph of a patient with bilateral pleural effusion shows increased homogeneous density of the lower hemithoraces.

Figure 3 Computed tomographic scan of the chest shows a free-flowing, sickle-shaped, right-sided effusion.

MRI is neither efficient nor cost-effective in standard evaluation of pleural effusion.^{12,14}

THORACENTESIS

If the cause of a pleural effusion cannot be explained by the clinical circumstances (e.g., congestive heart failure or a recent surgical procedure), diagnostic thoracentesis [see *Sidebar*

Figure 4 Chest computed tomographic scan of a patient with right-side empyema shows a loculated effusion. The pleura is enhanced with intravenous contrast.

Techniques for Bedside Thoracentesis and Tube Thoracostomy] is indicated. Thoracentesis may also have therapeutic value in that drainage of fluid may relieve dyspnea. Absolute contraindications to thoracentesis include a lack of cooperation on the patient's part, clinical instability with hemodynamic or respiratory compromise, severe coagulopathy, and high-pressure ventilation. Relative contraindications to thoracentesis include a nonlayering effusion, loculations, and previous thoracic trauma, chest tube placement, or surgery.

A large effusion can be drained without any special imaging guidance other than an upright posteroanterior and lateral chest radiograph. Thoracentesis for a small or loculated effusion is best done with ultrasound guidance; success rates are as high as 97%.¹⁵

The incidence of complications associated with thoracentesis varies, depending on the experience of the operator and on the use of imaging guidance. Pneumothorax occurs in 3 to 20% of patients, of whom approximately 20% require tube thoracostomy [see *Sidebar* Techniques for Bedside Thoracentesis and Tube Thoracostomy]. Patients commonly experience pain and cough with lung reexpansion during drainage. Reexpansion pulmonary edema is an uncommon complication that can occur with rapid drainage of a large-volume effusion. It is common practice to drain no more than 1 to 1.5 L at a time, even though no evidence supports this practice. Experimental data suggest that active aspiration of fluid can cause high negative intrapleural pressures, potentially precipitating edema formation; gravity drainage may be preferable to minimize the chance of edema. Additional potential complications include so-called dry tap, vasovagal reaction, hemorrhage, hypovolemia, and PSI.^{10,16–18}

PLEURAL FLUID ANALYSIS

Assessment of a pleural fluid sample is guided, to some extent, by the clinical context in which the pleural effusion occurs. When the cause of the effusion is unknown, evaluation of a pleural fluid sample typically includes measurement of total protein and lactate dehydrogenase (LDH) concentrations, a cell count with differential, cause-specific testing, and microbiologic and cytologic analysis.

Biochemical Analysis of Pleural Fluid

A total protein concentration higher than 3 g/dL is sometimes used as the main criterion for distinguishing a transudate from an exudate; however, the use of this criterion may result in misclassification of as many as 15% of effusions. According to Light and colleagues' criteria,¹⁹ which have a sensitivity of 99% and a specificity of 98% for identifying exudates, an effusion is an exudate if one of the following three findings is present:

1. A pleural fluid-to-serum protein ratio higher than 0.5
2. A pleural fluid-to-serum LDH ratio higher than 0.6
3. A pleural fluid LDH concentration higher than two thirds of the upper limit of the serum reference range

Techniques of Bedside Thoracentesis and Tube Thoracostomy

Bedside Thoracentesis

Bedside thoracentesis should be performed on a bed or an examination table (as a safeguard if hypotension develops). The patient should be upright and seated (provided that he or she is awake and cooperative), with the arms leaning comfortably on a bedside table and the back facing the surgeon.

The proper intercostal space for catheter insertion is determined through physical examination and radiologic evaluation of the effusion; generally, the ninth or 10th intercostal space in the midscapular line is a good choice. The area is prepared and anesthetized with 1% lidocaine, 3 to 5 mg/kg, with care taken not to injure the intercostal bundle. To confirm that the catheter is in the correct location, we recommend drawing a small amount of pleural fluid at the time of local anesthetic infiltration. Several thoracentesis kits with one-way valves are available. Fluid should be allowed to drain by gravity; however, to minimize the risk of reexpansion pulmonary edema, drainage should not exceed 1.5 L. Frequently, a dry cough and pleuritic pain develop as drainage approaches its end. To minimize anxiety, the patient should be warned about this possibility in advance. After the completion of thoracentesis, a chest radiograph should be obtained.

Bedside Tube Thoracostomy

Bedside tube thoracostomy should be performed with the patient supine. The side on which the thoracostomy will be created should be elevated, and the patient's ipsilateral arm should be abducted. Supplemental oxygen should be supplied. Monitoring must include, at the least, continuous oxygen saturation plethysmography and intermittent measurement of blood pressure and heart rate. Tube thoracostomy is potentially very painful; accordingly, in a nonemergency situation, every effort should be made to minimize pain and anxiety. We usually administer intravenous ketorolac about 30 to 60 minutes before the procedure. During preparation for chest tube placement, narcotics and sedatives should be administered intravenously; additional doses should then be administered at the beginning of and during the procedure.

The ideal location for chest tube placement is determined by clinical and radiographic examination. The area is prepared and draped widely, and a local anesthetic is used at a near-maximum dosage, with care taken to anesthetize skin, subcutaneous tissue, muscle, and periosteum. A 1.5 cm skin incision is made, a soft tissue tunnel is created with blunt instrument and finger dissection, the upper edge of the rib is identified clearly, and additional local anesthetic is applied to the periosteum and the intercostal muscles. The subcutaneous tunnel should generally be directed posteriorly so that the chest tube will sit along the posterior chest wall and will not be trapped in a fissure. The intercostal muscle is pierced bluntly, and digital examination of the pleural space is performed to confirm that an intrapleural location has been reached and to search for abnormalities such as adhesions or tumor implants. The chest tube is then directed to the desired location with the aid of a clamp. As with thoracentesis, fluid should be allowed to drain by gravity, but drainage should not exceed 1.5 L. If the effusion exceeds 1.5 L, the chest tube should be clamped and the remaining fluid allowed to drain intermittently in 200 mL aliquots every 2 hours. Immediately after completion of the procedure, a chest radiograph should be obtained to verify lung expansion and confirm the position of the chest tube. When chest tube output falls below 200 mL/day and reexpansion of the lung is verified, pleurodesis should be performed. We recommend that patient-controlled analgesia be employed while the chest tube remains in place.

The size of the chest tube is determined by the suspected cause and by the radiologic characteristics of the effusion. For a free-flowing transudative effusion, a small (20 to 24 French) chest tube or even a pigtail catheter usually suffices; for a thick exudative effusion or a hemothorax, a tube as large as 40 French may be required.

A 1997 meta-analysis of the diagnostic value of tests used to distinguish transudates from exudates did not find any test or combination of tests to be clearly superior.²⁰ The choice of a test for this purpose is therefore a matter of individual preference. If only one test is to be performed, measurement of the total protein concentration is the most practical choice in view of its accuracy and availability.

Assessment of pleural fluid pH and glucose levels may be used adjunctively for risk stratification in patients with PSI, but the clinical utility of these measurements is not well established (see below).²¹

There are numerous substances whose concentrations can be measured to help determine the specific cause of a pleural effusion, such as triglycerides, chylomicrons, and cholesterol (to help diagnose chylothorax); amylase (to help diagnose esophageal perforation or pancreatitis); rheumatoid factor (to help diagnose rheumatoid effusion); antinuclear antibodies (to help diagnose lupus pleuritis); carcinoembryonic antigen (to help diagnose malignancy); and adenosine deaminase (to help diagnose tuberculous pleurisy).^{3,22–25}

Cell Counts

Analysis of the number and type of white blood cells (WBCs) present in pleural fluid is often diagnostically useful. Pleural effusions can be categorized according to the type of WBC that is predominant. Generally, pleural fluid neutrophilia points to acute inflammation (e.g., from PSI or pulmonary infarction) as the underlying cause; however, the

presence of a neutrophilic effusion does not exclude malignancy. Pleural fluid lymphocytosis, in which lymphocytes account for more than 50% of WBCs, most frequently is indicative of malignancy (occurring in 50% of malignant effusions), tuberculosis (occurring in 15 to 20% of tuberculous effusions), or chylothorax.²⁶ Pleural fluid eosinophilia, in which eosinophils account for more than 10% of WBCs, can be caused by a wide variety of benign and malignant conditions—even, in some cases, by the mere presence of air or blood in the pleural space. Approximately one third of eosinophilic effusions are idiopathic. As a rule, the presence of mesothelial cells is of little diagnostic value; the exception to this rule is that if such cells account for more than 5% of WBCs, a tuberculous effusion is unlikely.^{23,27}

Microbiologic Tests

If a PSI is suspected, Gram staining and standard bacterial cultures are indicated. If tuberculous pleurisy is a possibility, acid-fast stains and mycobacterial cultures should be performed. Fungal, viral, and parasitic PSIs are uncommon; accordingly, special stains and cultures for these conditions are indicated only if dictated by a specific clinical setting.²⁸

Cytologic Tests

Cytologic testing of pleural fluid is routinely performed whenever the cause of an effusion is unclear. The diagnostic yield for malignancy varies depending on the stage of the disease, but it generally is in the range of 50 to 60% (higher in

patients with bulky pleural tumors). Repeat cytologic testing may increase the yield to more than 70%,^{10,29} and testing of three or more samples may increase the yield to 90%.³⁰

PLEURAL BIOPSY

In approximately 25% of patients with exudative effusion, the cause remains unknown after clinical evaluation, imaging, and pleural fluid analysis. The next step in the evaluation of such patients is pleural biopsy.

Percutaneous pleural biopsy is an infrequently used tool that has a diagnostic yield of 57% for carcinoma. Its low yield for malignant effusion can be explained by the uneven distribution of pleural metastases. For tuberculous pleurisy, however, the diagnostic yield of percutaneous pleural biopsy is 75%, and the yield rises to 90% when this procedure is combined with pleural fluid culture. In about 10 to 20% of patients with exudative pleural effusion, laboratory analysis of pleural fluid and percutaneous biopsy fail to produce a specific diagnosis.¹⁸ The contraindications and complications associated with percutaneous pleural biopsy are similar to those associated with thoracentesis.³¹

Video-assisted thoracoscopic surgery (VATS) is also employed for pleural biopsy; its diagnostic yield in this setting is 92% for malignancy and nearly 100% for tuberculous pleurisy. VATS is a therapeutic procedure as well, allowing the surgeon to perform pleurodesis, decortication, or pleurectomy if necessary. VATS pleural biopsy is typically performed with the patient under general anesthesia, but if the patient is highly debilitated, it can be done with regional and local anesthesia.³² Procedure-specific complications include hypoxemia, hemorrhage, prolonged air leakage, subcutaneous emphysema, and empyema, each of which occurs at a rate of about 2%. The mortality associated with diagnostic thoracoscopy ranges from 0.01 to 0.09%.^{29,31} When VATS is performed to remove a suspected malignant lesion, a protective plastic device is required to minimize the possibility of tumor seeding. Incisional tumor seeding after a VATS biopsy is rare but can occur at any time after the procedure (reported range 2 weeks to 29 months).³³

If mesothelioma is suspected, pleural biopsy (through a 5 cm incision) is the preferred diagnostic procedure. Ideally, the biopsy incision should be placed at the location of a potential thoracotomy incision so that future excision of the biopsy scar can be accomplished in a manner that minimizes the risk of local tumor recurrence.³⁴

Management

PLEURAL EFFUSION IN THE INTENSIVE CARE UNIT

Pleural effusion develops in as many as 60% of intensive care unit (ICU) patients evaluated with ultrasonography.¹¹ When pleural effusion occurs in the ICU, drainage should be liberally employed to optimize the patient's hemodynamic and respiratory status and to detect PSI early. Thoracentesis can be done in critically ill ventilator-dependent patients with the help of bedside

ultrasonography. Chest tube thoracostomy does not require ultrasonographic guidance and may be a safer choice for patients on high-pressure ventilation.

MALIGNANT PLEURAL EFFUSION

Pleural effusion is associated with malignancy in 30 to 65% of patients, and approximately 75% of patients with malignant effusion have lung or breast cancer.³⁵ The principal aim of therapy is to relieve dyspnea and to limit the number of procedures and hospital days that patients with a limited life expectancy must endure.

Drainage can be achieved by means of thoracentesis, chest tube placement, or VATS. Thoracentesis is a valuable option for initial patient evaluation, particularly in the office setting. Because malignant pleural effusion recurs rapidly unless patients undergo effective systemic or local treatment, repeat thoracentesis is generally not recommended for anything other than urgent relief of symptoms. Chest tubes are placed primarily with the intention of performing bedside pleurodesis.

Small-bore subcutaneously tunneled catheters may be employed for long-term management of malignant pleural effusions. Long-term drainage is preferable in patients with a very short life expectancy (≤ 3 months), patients who have a poor performance status, and patients with a trapped lung.³⁶ Two options are available: the Pleurx catheter (Denver Biomedical, Golden, Colorado) [see Figure 5] and the Tenckhoff peritoneal dialysis catheter. With either device, the procedure is essentially the same: the catheter is inserted with the patient under local or general anesthesia, the patient is discharged on the day of or the day after insertion, and the pleural fluid is drained either according to a schedule or on an as-needed basis. Small-bore tunneled catheters are comfortable, but patients may object to having a permanent catheter or to undergoing home-based procedures. In 20 to 70% of patients with a permanent catheter, pleurodesis develops within 4 to 6 weeks. Patients with malignant pleural effusions secondary to breast or gynecologic cancers are more likely to develop pleurodesis (about 70%) than patients with lung cancer (about 40%).³⁷ Catheter removal is easily done in the office setting with local anesthetic. Technical failures and infection

Figure 5 Shown is a Pleurx catheter after placement and subcutaneous tunneling. The vacuum container is not connected.

may occur in as many as 20% of patients with permanent catheters, but very few patients require operative management.^{38–41}

Pleuroperitoneal shunting has been advocated as an alternative for long-term management of malignant pleural effusions. However, experience with this mode of drainage is limited and the potential for technical complications is high.^{42,43}

Recurrence of malignant pleural effusion is best prevented by using sclerosants to induce pleurodesis. The sclerosant may be instilled either via a bedside tube thoracostomy or thoroscopically; a median hospitalization of 6.5 days is required.³⁸ Of the various sclerosants available, talc is the most efficacious, with an overall success rate of 80 to 96%.^{44–46} The ideal talc dose has not been determined; the usual dose is 4 or 5 g. Talc pleurodesis with a 5 g dose has generally proved efficient and safe. For obvious reasons, simultaneous bilateral talc instillation should be avoided.⁴⁴ A phase III intergroup study (Cancer and Leukemia Group B 9334) that compared bedside talc slurry pleurodesis versus thoroscopic talc insufflation pleurodesis found no difference in outcome at 30 days; however, subgroup analysis revealed that thoroscopic talc insufflation pleurodesis was superior in patients with primary lung cancer or breast cancer.⁴⁷ Thoroscopically guided talc pleurodesis can be performed with an operative mortality of less than 1%.^{48,49}

Pain and fever are frequent side effects of talc pleurodesis, but the main concern is the possible development of acute lung injury (ALI) and respiratory failure. Respiratory failure is reported to occur in approximately 1 to 4% of patients. The cause of respiratory failure secondary to talc pleurodesis is not clear and is probably related to multiple factors (e.g., talc dose, talc absorption, underlying lung disease, reexpansion pulmonary edema, systemic inflammatory response, tumor burden, and lymphatic obstruction). There is no definitive evidence that the talc dose is correlated with the incidence of ALI; respiratory failure has been reported even with a 2 g talc dose.^{44,50–54} Moreover, a recent multicenter prospective cohort study reported a 0% incidence of acute respiratory distress syndrome in 558 patients undergoing talc pleurodesis (4 g dose).⁵⁵

Iodopovidone (10%; 20 mL) is a very effective and inexpensive alternative for chemical pleurodesis that is of value in the setting of limited financial resources.^{56,57}

Treatment of malignant pleural effusion must be individualized. The key factors governing the choice of treatment approach are the (1) patient's performance status, (2) prognosis, (3) patient's choice, (4) ability of the lung to reexpand, and (5) pleural tumor bulk. Patients who have poor performance status (e.g., those with advanced tumors or significant comorbid conditions) or a very poor short-term prognosis should undergo the least invasive treatment—namely, drainage only. Patients who have better functional status and are expected to survive longer should preferably undergo thoroscopically guided talc pleurodesis, but it is not unreasonable for a patient to elect to have long-term drainage in this scenario. Pleural tumor bulk is important in that bulky pleural lesions will interfere with pleurodesis. The lung's ability to reexpand after drainage of a malignant effusion is significant because if the lung is atelectatic as a result of airway obstruction or trapped as a result of pleural seeding, no agent will be able to induce pleurodesis, and the best treatment will be

long-term drainage. Table 3 summarizes practical guidelines for the definitive management of malignant pleural effusion.

PLEURAL SPACE INFECTION

PSI can be caused by a variety of factors, including pneumonia, trauma, and intrathoracic procedures. It has a wide clinical spectrum, ranging from a small parapneumonic effusion (PPE) to a pus-filled pleural space (empyema) with respiratory compromise and sepsis. (The terms PSI and PPE are often used interchangeably.) PSI can be classified according to its pathophysiologic stage (exudative, fibrinopurulent, or organizing) or its anatomic appearance (nonloculated versus loculated or noncomplicated versus complicated). The term empyema is commonly reserved for the most advanced stage of PSI.⁵⁸

The pathophysiology of PSI or PPE can be divided into three stages. The exudative stage is characterized by the development of an exudative effusion secondary to increased pleural permeability; the pleural space is often sterile initially, but if it is left untreated, bacterial infection is likely to ensue. The fibrinopurulent stage is marked by the progressive deposition of fibrin and the increasing presence of WBCs; gradual angioblastic and fibroblastic proliferation leads to extensive fibrin deposits, and the effusion becomes loculated (complicated). The organizing stage starts as early as 1 week after infection, with increasing collagen deposition and lung entrapment; after 3 or 4 weeks, the organized collagen has formed a peel. The pleural fluid is grossly purulent. Eventually, dense fibrosis, contraction, and lung entrapment develop.^{59,60}

In most patients, PSI is caused by bacteria. The most common pathogens are *Staphylococcus aureus*, *Streptococcus pneumoniae*, enteric gram-negative bacilli, and anaerobes. Approximately 30 to 40% of cultures are polymicrobial. In a subgroup of patients, there is sterile pus in the pleural space as a consequence of either previous antimicrobial therapy or bacterial autolysis. The pathogens identified vary according to the cause of PSI. For instance, *S. aureus* and *S. pneumoniae* predominate in PPE, *S. aureus* in postthoracotomy PSI, mixed oropharyngeal organisms in PSI resulting from esophageal perforation,²⁸ and acid-fast bacteria in tuberculous empyema.⁶¹

Parapneumonic Effusion

PPE occurs in as many as 57% of patients hospitalized with pneumonia, and pneumonia accounts for 42 to 73%

Table 3 Practical Guidelines for Definitive Management of Malignant Pleural Effusion

Patient Characteristics	Chemical Pleurodesis	Long-Term Drainage
Performance status		
Good	Yes	Yes
Poor	No	Yes
Life expectancy		
> 6 mo	Yes	Yes
3–6 mo	Individualize	Yes
< 3 mo	No	Yes
Bulky pleural implants	Individualize	Yes
Trapped lung	No	Yes

of cases of PSI. In most cases, early PPE is effectively treated by timely antibiotic therapy aimed at the underlying pneumonia.^{21,28}

In 2000, a panel convened by the Health and Science Policy Committee of the American College of Chest Physicians (ACCP) reviewed the available literature with the aim of developing an evidence-based clinical practice guideline for the treatment of PPE.²¹ The panel formulated a clear and relatively simple classification system that used pleural anatomy and bacteriology to stratify patients according to the risk of a poor outcome [see Table 4]. It then made therapeutic recommendations on the basis of this classification. Some authors have used pleural fluid chemistry test results (e.g., pH and glucose concentration) as additional criteria for categorizing PPE; for example, a pleural fluid pH lower than 7.20 or a glucose level lower than 60 mg/dL has been considered suggestive of moderate risk. To date, however, the clinical utility and decision thresholds of pH and glucose values have not been well defined. Accordingly, the panel omitted pleural fluid chemistry from its guidelines.

The ACCP Health and Science Policy Committee evaluated six primary management approaches: no drainage, therapeutic thoracentesis, tube thoracostomy, fibrinolytic therapy, VATS, and open surgery. Overall, pooled outcomes favored patients treated with fibrinolytics, VATS, and open surgery. However, the success of an approach is related to the patient's risk category. The recommendations for drainage in relation to risk category are general guidelines, based on level C and D evidence (with level C referring to historically controlled series and case series and level D to expert opinion). With these recommendations (and their limitations) in mind, treatment should be tailored to the specific situation of each patient.

Category 1 and 2 PPE PPE in categories 1 (very low risk) and 2 (low risk) can be treated with antibiotic therapy directed at the underlying pneumonia. Some patients with category 2 PPE may require drainage for relief of dyspnea through either thoracentesis or tube thoracostomy.

Category 3 and 4 PPE Drainage options for category 3 (moderate risk) and 4 (high risk) PPE include tube thoracostomy alone, tube thoracostomy with intrapleural fibrinolytic therapy, VATS drainage, and open surgical drainage. These various approaches are not mutually exclusive: in some cases, patient outcomes may be optimized by a combination of treatment modalities.⁶²

Tube thoracostomy alone may be appropriate for category 3 patients with free-flowing effusion. With loculated effusion, however, the key to successful therapy is breaking down the fibrin septations. Evidence from three small randomized, controlled trials suggested that intrapleural fibrinolytic therapy has an advantage over tube thoracostomy alone for patients with category 3 or 4 PPE; a large trial is being conducted to address this specific issue.⁵⁹ To date, only one randomized study, including 20 patients with category 3 or 4 PPE, has compared VATS with fibrinolytic therapy. The primary treatment success rate was significantly higher in the VATS treatment group, the duration of chest tube drainage was less, and the total hospital stay was shorter.⁶³ VATS allows not only adequate drainage and visualization of the pleural space but also decortication of the lung if required; however, if decortication cannot be thoroughly accomplished by means of VATS and satisfactory lung expansion cannot be achieved, a thoracotomy should be performed.^{64,65}

The principles of PPE treatment can be applied to PSI from any cause, but in view of the paucity of reliable data, caution should be exercised.

Posttraumatic PSI

PSI occurs in about 1 to 5% of patients who have sustained blunt or penetrating thoracic injury. The incidence of PSI in the setting of trauma increases with the number of chest tubes placed and with the duration of chest tube drainage. The effect of an undrained hemothorax on the risk of PSI has not been completely defined, and prophylactic antibiotics have not been shown to reduce the incidence of PSI.⁵⁸

As noted (see above), the general guidelines for the treatment of PPE apply to the treatment of posttraumatic PSI.

Iatrogenic PSI

Iatrogenic PSI develops when a preexisting pleural effusion is inoculated with bacteria during an invasive procedure (e.g., thoracentesis or tube thoracostomy). The presence of fluid in the pleural space appears to be a prerequisite for infection.⁵⁸

A bronchopleural fistula (BPF) is by definition a PSI and therefore has a similarly broad spectrum of clinical presentation. The overall incidence of BPF after lobar resection is approximately 1%; it is somewhat higher after resections for inflammatory diseases than after resections for cancer. The incidence of BPF after pneumonectomy varies depending on the side on which the pneumonectomy was done, the indications for surgery, the extent of preoperative irradiation,

Table 4 Categorization of Parapneumonic Effusion by Risk of Poor Outcome

Pleural Space Anatomy	Pleural Fluid Bacteriology	Category	Risk of Poor Outcome	Drainage
Minimal free-flowing effusion (< 10 mm on lateral decubitus x-ray)	Culture and Gram stain results unknown	1	Very low	No
Small to moderate free-flowing effusion (> 10 mm but < 50% hemithorax)	Negative culture and Gram stain	2	Low	No
Large free-flowing effusion (> 50% hemithorax), loculated effusion, or effusion with thickened parietal pleura (as seen on contrast-enhanced CT)	Positive culture or Gram stain	3	Moderate	Yes
	Pus	4	High	Yes

CT = computed tomography.

and the comorbid conditions present. In a report encompassing 464 pneumonectomies for cancer, the incidence of BPF was 8.6% after right pneumonectomy and 2.3% after left pneumonectomy.^{66,67}

Almost every PSI after a lung resection is synonymous with BPF, and operative management is generally required.

Tuberculous PSI

Pleural effusion is common in patients with clinically evident pulmonary tuberculosis. Most cases of tuberculous effusion are secondary to hypersensitivity and resolve spontaneously. Tuberculous empyema is relatively rare; it is typically the result of active pleural infection by acid-fast bacteria.⁶¹

Tuberculous PSI is also treated in accordance with the general treatment guidelines for bacterial PSI. Chronic tuberculous PSI may present specific problems, such as drug resistance and impaired ability (or even inability) to reexpand the lung. Surgical procedures performed to manage chronic tuberculous empyema include VATS, standard open decortication, thoracoplasty, parietal wall collapse, open drainage, myoplasty, and omentopexy.⁶¹

CHYLOTHORAX AND PSEUDOCYLOTHORAX

Chylothorax is the presence of chyle in the pleural space as a consequence of blockage of or damage to the thoracic duct or one of its tributaries. The rate at which chyle flows through the thoracic duct can be higher than 100 mL/hr; thus, large amounts of chyle can leak into the pleural space.⁶⁸ The principal causes of chylothorax are surgical trauma and malignancy (70 to 80% are caused by non-Hodgkin lymphoma).^{49,68,69} Congenital chylothorax is more often attributable to malformation of the thoracic duct than to birth trauma.²⁴

The diagnosis of chylothorax is made by measuring triglyceride levels in pleural fluid. Levels higher than 110 mg/dL are highly suggestive of chylothorax, levels between 50 and 100 mg/dL are equivocal, and levels lower than 50 mg/dL rule out chylothorax.²⁴ A pleura-to-serum triglyceride ratio higher than 1 can be a useful indicator⁷⁰; the presence of chylomicrons is synonymous with chylothorax.²⁵

Treatment of chylothorax depends on its cause and severity. Postoperative chylothorax may be treated initially with conservative measures (e.g., with a nihil per os [NPO] regimen, total parenteral nutrition, and administration of octreotide). However, drainage totaling more than 500 mL/day is considered to predict failure of conservative management. Thoracic duct ligation is the surgical treatment of choice and can often be performed thoracoscopically. To help identify the leak intraoperatively, it may be helpful to administer 100 to 200 mL of heavy cream or olive oil orally 2 to 3 hours before operation.^{71,72} Early surgical intervention is important because the ongoing loss of lymph has significant effects on fluid homeostasis, nutrition, and immunocompetence (secondary to lymphocyte loss). In the early postligation period, medical management should be continued to allow any small leaks to seal. An alternative to surgical ligation that has evoked some interest is transabdominal percutaneous embolization of the thoracic duct. This technique requires significant expertise.⁷³

Lymphoma-related chylothorax is caused principally by obstruction and usually develops on the left side [see *Figure 6*]. In a stiff and infiltrated duct, minor triggers (e.g., a Valsalva maneuver) can lead to duct rupture. Although patients with chylothorax often have extensive disease, supradiaphragmatic disease is not always present. Lymphoma-related chylothorax is best managed with thoracentesis and with therapy directed at the underlying cause. If first-line therapy fails, thoracoscopic talc pleurodesis is recommended; a small series reported 100% resolution of lymphoma-related chylothorax with thoracoscopic talc pleurodesis. If the chylothorax does not respond to any of these approaches, it may respond to thoracic duct ligation or pleuroperitoneal shunting. Chylothorax in the presence of lymphoma-related chylous ascites is a difficult problem that is generally refractory to most forms of therapy (although pleurodesis is occasionally successful).^{49,68,69,74,75}

Pseudochylothorax is a rare disorder associated with the formation of persistent exudates that last for months or years. The most common cause is tuberculosis; the second most common cause is rheumatoid arthritis. Biochemical analysis of pleural fluid from patients with pseudochylothorax reveals very high cholesterol levels (> 200 mg/dL) and the presence of cholesterol crystals. Treatment is generally conservative.^{24,25}

IDIOPATHIC PERSISTENT PLEURAL EFFUSION

In a small percentage of patients, the cause of pleural effusion remains unknown despite extensive diagnostic evaluation. Eventually, most cases of idiopathic effusion turn out to be caused most frequently by tuberculosis and other granulomatous diseases, malignancy, and pulmonary embolism; less common causes include constrictive pericarditis, subphrenic abscess, connective tissue diseases, drug-induced pleuritis, peritoneal dialysis, and cirrhosis.²³ In the management of persistent benign or idiopathic effusion, talc pleurodesis has a high success rate and minimal long-term implications.^{76,77} A chronic drainage catheter (i.e., Pleurx) can be used for refractory pleural effusion in patients with congestive heart failure; however, prolonged use (> 4 months) can lead to empyema.⁷⁸

Figure 6 Chest computed tomographic scan shows left-side chylothorax secondary to lymphoma. Subtle mediastinal lymphadenopathy obstructing the thoracic duct (arrow) is apparent.

Hence, in the setting of a benign, refractory pleural effusion, a chronic drainage catheter should be considered only as a last resort.

Pleura: Basic Facts

PLEURAL ANATOMY

The pleura is a continuous membrane that covers the parietal and visceral surfaces of the thorax. In adults, it has an estimated surface area of 2,000 cm².⁷⁹ Light microscopy shows the pleura to have five layers: (1) a mesothelial cell layer; (2) a mesothelial connective tissue layer with basal lamina; (3) a superficial elastic layer; (4) a loose connective tissue layer with adipose tissue, blood vessels, nerves, and lymphatic vessels; and (5) a deep fibroelastic layer. The parietal pleura establishes a pleurolymphatic communication on the diaphragm to allow clearance of large (> 1,000 nm) particles and cells from the normal pleural space. The structure of this pleurolymphatic communication consists of stomata 2 to 12 µm in diameter, which overlie bulblike lymphatic channels (lacunae) separated by a layer of loose connective tissue (the membrana cribriformis).

Electron microscopy reveals microvilli on the mesothelial cell surface of the pleura. The main function of these microvilli is to enmesh glycoproteins rich in hyaluronic acid for

purposes of lubrication. The structure of the intercellular junction in the mesothelial cells of the pleura is similar to that in the endothelial cells of the venules, which suggests that the pleural mesothelial cell layer may be as leaky as the venular endothelium.^{3,4,80}

PLEURAL FLUID PHYSIOLOGY

The amount of pleural fluid in an adult is 1 to 10 mL and forms a 10 µm thick layer.^{1,3,79,80} Fluid exchange across the pleural surface depends on three mechanisms: (1) passive filtration following Starling equilibrium, (2) active solute transport, and (3) lymphatic clearance. In the normal pleura, Starling equilibrium favors the flow of fluid in a parietal-to-visceral direction.⁷⁹ The rate at which fluid traverses the pleura ranges from 20 to 160 mL/day in adults; maximal lymphatic clearance is believed to be approximately 700 mL/day.^{2,79,81–84}

The chemical composition of normal pleural fluid is similar to that of interstitial fluid. The protein concentration is typically 1 to 2 g/dL. The concentration of high-molecular-weight proteins (e.g., LDH) is approximately half that seen in serum. Cell counts in normal pleural fluid range from 1,400 to 4,500 cells/µL; macrophages account for the majority of the cells.^{3,80}

5 SOLITARY PULMONARY NODULE

Taine T.V. Pechet, MD, FACS*

Assessment of a Solitary Pulmonary Nodule

The solitary pulmonary nodule (SPN) is a common finding that is observed in more than 150,000 persons each year in the United States.¹ An SPN is defined as a single radiographically visible pulmonary lesion that is less than 3 cm in diameter, is completely surrounded by pulmonary parenchyma, and is not associated with atelectasis or adenopathy.² Any pulmonary lesion larger than 3 cm is considered a mass and as such has a greater likelihood of being malignant.^{3,4} SPNs are detected on routine chest radiography at a rate of 1 in 500 x-rays, but with the growing use of computed tomographic (CT) scanning, they are now being diagnosed with increasing frequency.

The differential diagnosis of an SPN is broad and includes vascular diseases, infections, inflammatory conditions, congenital abnormalities, benign tumors, and malignancies [see Table 1]. Although most SPNs are benign, as many as one third represent primary malignancies, and nearly one quarter may be solitary metastases.^{1,5,6} Various approaches have been developed to aid in the characterization and identification of SPNs. Certain clinical characteristics—such as greater age, history of tobacco use, and previous history of cancer—have been shown to increase the likelihood that the SPN is malignant.⁷ Some authors have attempted to use the Bayes theorem, logistic regression models, or neural network analysis to predict the likelihood of malignancy.⁷⁻⁹ Such methods are highly sensitive and specific, but they are cumbersome and of limited clinical applicability.

Clinical Evaluation

Once an SPN has been identified, it is necessary to determine whether the lesion is benign or malignant and what further investigations should be pursued. Evaluation should generally be governed by the dictum “malignant until proven otherwise.” The basis for an initial assumption of malignancy is the observation that the overall 5-year survival rate is low (10 to 15%) once a diagnosis of lung cancer is established.¹⁰ Appropriate evaluation involves careful assessment of the patient’s history and risk factors for malignancy in conjunction with the results of radiographic studies [see Investigative Studies, below] to develop an individualized care plan.

* The authors and editors gratefully acknowledge the contributions of the previous author, Shamus Carr, MD, to the development and writing of this chapter.

Table 1 Differential Diagnosis of Solitary Pulmonary Nodule

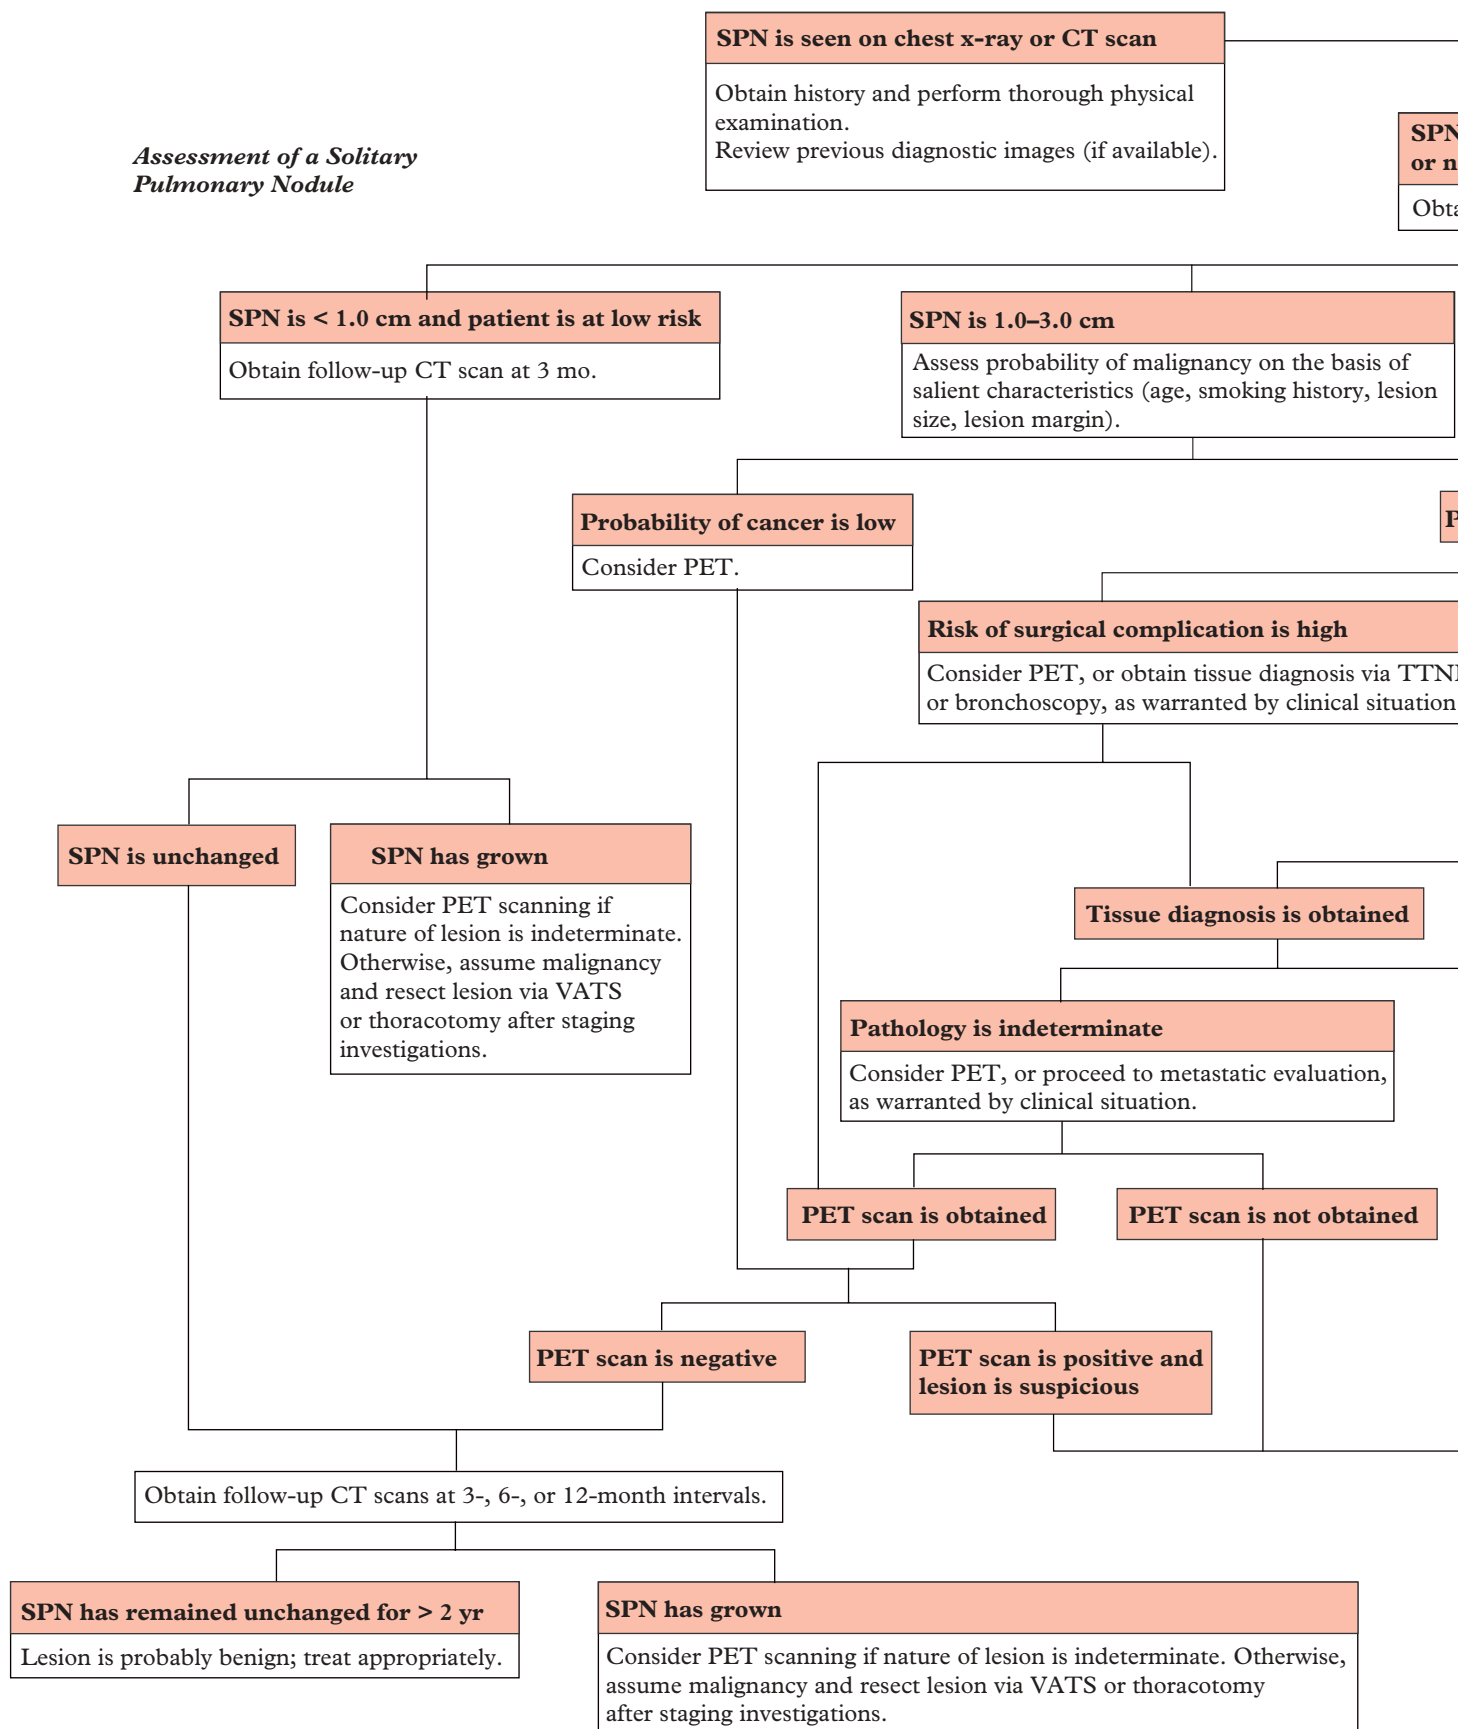

Behavior	Category	Disease
Benign	Vascular disease	Arteriovenous malformations Pulmonary artery aneurysm
	Infection	<i>Mycobacterium avium</i> complex infection Aspergilloma Histoplasmosis Echinococcosis Blastomycosis Cryptococcosis Coccidioidomycosis Ascariasis Dirofilariasis
	Inflammatory condition	Rheumatoid nodule Sarcoidosis Wegener granulomatosis
	Congenital abnormality	Foregut duplication cyst
	Other	Rounded atelectasis Pulmonary amyloidosis
	Benign tumor	Hamartoma Lipoma Fibroma
Malignant	Primary lung cancer	Non-small cell lung cancer Squamous cell carcinoma Adenocarcinoma Large cell cancer Bronchoalveolar carcinoma Small cell lung cancer Carcinoid Lymphoma
	Metastatic cancer	Colon cancer Testicular cancer Melanoma Sarcoma Breast cancer

FACTORS INFLUENCING PROBABILITY OF MALIGNANCY

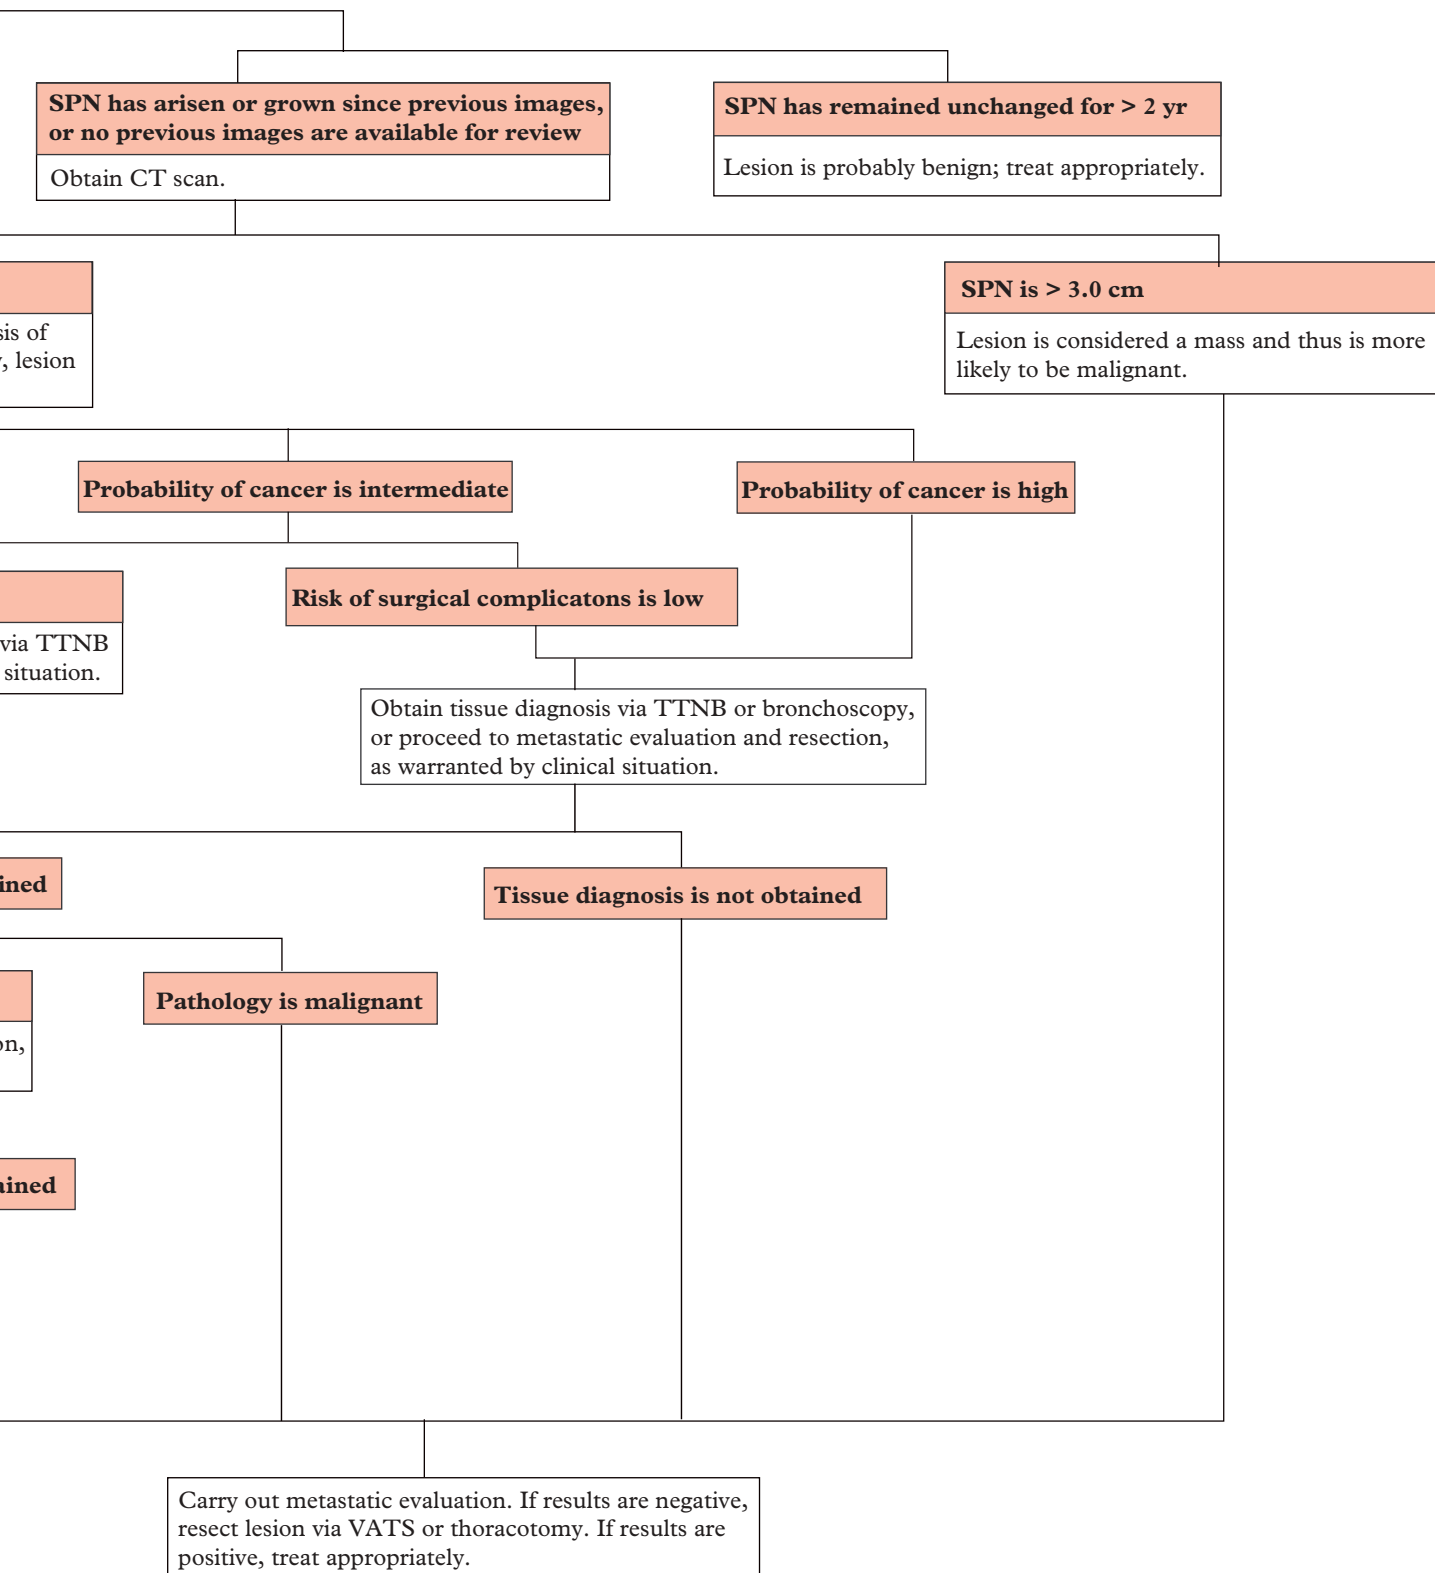

A number of factors influence the probability that an SPN is malignant. Those most strongly associated with lung cancer are age, smoking history, and occupational history. Pulmonary function test results indicative of a severe obstructive ventilatory impairment are also associated with an increased likelihood of malignancy.¹¹ In addition, the presence of endemic granulomatous disease has been shown to increase the probability that an SPN is harboring cancer.⁷

The radiographic appearance of an SPN, particularly on a CT scan, also influences the probability of malignancy

*Assessment of a Solitary
Pulmonary Nodule*

SPN = solitary pulmonary nodule; CT = computed tomography; PET = positron emission tomography; VATS = video assisted thoracic surgery; TTNB = trans-thoracic needle biopsy.

[see Investigative Studies, Imaging, Computed Tomography, below]. The size, contour, internal characteristics, and growth rate of the nodule are all potentially significant indicators of malignant disease [see Table 2].

Age

Lung cancer is rare before the age of 40 years, but its incidence steadily increases from that point until the age of 80.⁵ Above the age of 70, the likelihood that an SPN is malignant increases.⁸ After the age of 80, the incidence of malignancy in an SPN seems to level off or even decrease.¹²

Environmental Exposures

The link between cigarette smoking and lung cancer has been well established since the 1950s, and the incidence of lung cancer in smokers is directly correlated with the number of pack-years of smoking.¹³ The surgeon general's report from 2004 states that "the evidence is sufficient to infer a causal relationship between smoking and lung cancer."¹⁴ There is also ample evidence of a causal relationship between environmental tobacco exposure, termed "secondhand smoke," and lung cancer.¹⁵

Radon exposure is the second leading cause of lung cancer in America, and cigarette smoking further increases the risks associated with radon exposure.¹⁶ Asbestos exposure in combination with cigarette smoking also places patients at significantly increased risk for lung cancer. Patients with a history of workplace exposure to a radioactive substance (e.g., uranium or plutonium) are at increased risk for lung cancer, but this association is not as well documented as the association of lung cancer with tobacco use. Miners of heavy metals (e.g., nickel, cadmium, and silica) are also at increased risk, and a variety of other environmental toxins, from diesel exhaust through vinyl, have been associated with the development of lung cancer.¹⁵ There is some evidence to suggest that patients with idiopathic pulmonary fibrosis and pneumoconiosis are at increased risk for bronchoalveolar cell carcinoma.¹⁷

Table 2 Factors Affecting Malignant Probability of Solitary Pulmonary Nodule⁸

Factor	Likelihood Ratio for Malignancy
Spiculated margins on CT scan	5.54
Age > 70 yr	4.16
Lesion size 2.1–3.0 cm	3.67
Doubling time < 465 days	3.40
History of smoking	2.27
Age 50–69 yr	1.90
Lesion size 1.1–2.0 cm	0.74
Lesion size < 1 cm	0.52
Smooth margins on CT scan	0.30
No history of smoking	0.19
Doubling time > 465 days	0.01

CT = computed tomographic.

Investigative Studies

IMAGING

Chest Radiography (X-Ray)

Whereas the prevalence of lung cancer is low in comparison with that of breast or prostate cancer, the mortality for lung cancer exceeds that for breast, prostate, and colon cancer combined. As noted [see Clinical Evaluation, above], the overall 5-year survival rate for lung cancer patients is poor, in part because lung cancer is frequently diagnosed at a more advanced stage than other forms of cancer. Several trials performed before the advent of CT scanning evaluated chest radiography for early screening of lung cancer but were unable to demonstrate that such screening yielded better survival.^{18–20} One explanation for these disappointing results may be that fewer than 10% of lung cancers are stage I at presentation.¹⁸

Although chest radiography is ineffective as a screening tool for early-stage lung cancer, it remains a valuable investigative tool in the evaluation of SPNs. If an SPN's appearance on chest x-rays has not changed for more than 2 years, the SPN will be benign in more than 90% of cases. In such cases, only yearly follow-up is typically required; additional diagnostic tests are usually unnecessary.^{21,22} Therefore, an effort should always be made to obtain old chest radiographs if they are known to exist.

Computed Tomography

The advent of CT scanning has led to an increase in the number of SPNs detected.²³ But, of course, it has also led to an increase in the number of benign SPNs found. Advocates of CT scanning for assessment of SPNs base their argument on two central points. First, as many as 83% of CT-detected stage I malignancies are not visible on chest x-ray.²⁴ Second, non-small cell lung cancer (NSCLC) is the malignancy most commonly identified, and the survival rate for stage I NSCLC is relatively high in comparison with more advanced disease stages. In patients whose SPN proves to be NSCLC, the 5-year survival rate is 67% for stage IA disease. This figure falls rapidly as the disease stage rises: the 5-year survival rate is 55% for stage IIA NSCLC and only 10% for stage IIIA NSCLC with mediastinal nodal metastasis.²⁵

Numerous studies have evaluated the use of screening CT both in the general population and in at-risk groups consisting of older patients with a smoking history.^{24,26,27} The greatest drawback to screening CT is the high false positive rate: nodules are identified on 23 to 66% of all CT scans, depending on the thickness of the slices,^{12,24} and nearly 98% of these nodules are eventually determined to be benign. Sequential CT scanning is often required to determine whether an SPN is benign or malignant. In 10 to 15% of patients, however, this determination cannot be made even when two CT scans are compared. Such patients may be assessed with other imaging modalities (e.g., positron emission tomography [PET]) or may be referred for transthoracic needle biopsy (TTNB) or other invasive diagnostic tests.

Controversy exists in both the literature and in clinical practice around the optimal intervals for follow-up CT scanning after initial identification of an SPN. In the literature, the recommended interval between initial CT scanning and repeat CT scanning has ranged from 1 month to 1 year.^{12,24,27} These varying recommendations are based on what is considered the doubling time for an SPN. In a study from 2000 that included 13 patients with a known diagnosis and lesions less than 10 mm in diameter at initial evaluation, volumetric growth rates were measured to establish the doubling times of the nodules.¹⁰ The doubling times ranged from 51 days to more than 1 year. For malignant lesions, the average doubling time was less than 177 days, whereas for benign lesions, it was more than 396 days. New volumetric modeling methods have been developed that may be capable of detecting conformational changes over much shorter intervals, but they remain infrequently used.²⁸ Because the doubling time is considerably shorter for malignant lesions than for benign lesions, a repeat CT scan should typically be performed for most lesions 3 months after the initial study. If the lesion is visibly larger on the repeat scan, it is likely malignant, and diagnostic evaluation should progress toward presumed resection. If, however, the lesion has neither regressed nor progressed, a follow-up CT scan closer to 12 months is warranted; the precise timing remains controversial and should be determined on the basis of individual patient and SPN characteristics. The Fleischner Society Statement from the Radiological Society of North America provides commonly cited guidelines for the radiographic evaluation of nodules, with recommendations divided into size categories and recommendations that range from 3 to 12 months.²⁹

The morphologic characteristics of an SPN visualized on a CT scan can be extremely helpful in characterizing the probability of malignancy [see Differential Diagnosis, *below*]. Size, margin appearance, cavitation, and attenuation are important criteria. Air bronchograms, ground-glass opacity, and adjacent vascular distortion patterns can also help suggest malignancy. Although an SPN with a spiculated margin is perhaps most suspicious for malignancy, one fifth of lung cancers may have well-defined margins.^{30,31} Within areas of ground-glass opacity, characteristic changes, such as the development of nodularity and solid attenuation, have been identified that increase the probability of malignancy.^{32–34} Other CT characteristics may point more toward a benign condition. For example, although cavitation may occur in either benign or malignant lesions, SPNs with walls thinner than 4 mm are much more likely to be benign, whereas those with walls thicker than 16 mm are more likely to be malignant.³⁵ Intranodular fat is a reliable indicator of a hamartoma, a benign lesion, and is seen in as many as 50% of hamartomas.³⁶ In addition, calcification is most commonly associated with hamartomas and other benign nodules. Unfortunately, between one third and two thirds of benign lesions visualized are not calcified, and as many as 6% of malignant lesions are calcified.^{31,37,38} Finally, increased enhancement (measured in Hounsfield units [HU]) after injection with intravenous contrast is strongly suggestive of malignancy and has been included in the American College of Chest Physicians (ACCP) consensus recommendations.³⁹ Lesions that enhance by less than 15 HU are most likely benign (positive predictive value 99%), whereas lesions that enhance by more than 20 HU

are typically malignant (sensitivity 98%; specificity 73%).⁴⁰ Lesions that enhance by 15 to 20 HU should be considered indeterminate.

Because most SPNs are benign and because the risk of misdiagnosing a malignant lesion is so great, it is important to make use of all of the data obtained from CT scanning in the effort to make cost-effective, logical decisions regarding further evaluation or treatment. Careful evaluation of the size, contours, and internal characteristics of an SPN on successive CT scans, balanced by the patient's risk profile, including age, smoking history, and environmental exposures, provides the framework for developing an individualized evaluation strategy

Positron Emission Tomography

PET is an imaging modality that employs radiolabeled isotopes of fluorine, carbon, or oxygen; the most commonly used isotope is ¹⁸F-fluorodeoxyglucose (FDG). The rationale for FDG-PET scanning in the evaluation of SPNs is based on the higher metabolic rate of most malignancies and the preferential trapping of FDG in malignant cells.⁴¹ However, increased FDG activity can also occur in benign SPNs,^{42,43} especially those arising from active granulomatous diseases^{44,45} or inflammatory processes.⁴⁶ These benign diseases can produce false positive PET scans and thereby reduce the sensitivity of the test. Conversely, some malignancies—bronchoalveolar carcinoma and carcinoid tumors, in particular—have low metabolic activity and commonly produce false negative PET scans.^{47–51} Thus, a negative PET scan is not a particularly helpful result, and it is necessary to follow the lesion with serial CT scans. Accuracy calculations for PET scanning vary widely, with some of the highest sensitivity and specificity figures reported in an early meta-analysis identifying sensitivity of 96% and specificity of 77%.⁵² More recent pooled sensitivity and specificity figures were 87% and 83%, with specificity ranging from 40 to 100%.³⁹

Efforts have been made to improve the sensitivity and specificity of PET scanning in the diagnosis of SPNs. One such effort involves the use of the standardized uptake value (SUV), which is a numerical indication of the activity concentration in a lesion, normalized for the injected dose.⁵³ In many studies, an SPN is considered malignant when its SUV is higher than 2.5. Because of the methodology used to calculate SUV, however, small tumors (< 1.0 cm) may have an SUV lower than 2.5 and still be malignant. Their small volume causes their true activity concentration to be underestimated, with the result that their SUV drops below the threshold value for malignancy. In one prospective study of patients with SPNs, the overall sensitivity of FDG-PET scanning was 79% and the overall specificity was 65%.⁵⁴ When the SPN was smaller than 1.0 cm, however, all of the scans were negative, even though 40% of the nodules were malignant. Another effort involves recent technology combining PET and CT scans. CT-PET fusion imaging is clinically available in many locales, and combination imaging has been found to be particularly important for staging.^{55,56}

In cases where the SPN is larger than 8 mm and no previous radiographs or CT scans are available for comparison, PET scanning can provide information that may facilitate the decision whether to follow the lesion closely or to proceed with tissue acquisition. ACCP consensus recommendations

include the use of PET scanning in select lesions greater than 8 mm identified in patients with low to moderate pretest probability of malignancy.³⁹ Cost analysis is also an important criterion in considering PET scanning. One study that examined the cost-effectiveness of PET in the evaluation of SPNs concluded that it was cost-effective for patients who had an intermediate pretest probability of a malignant SPN and who were at high risk for surgical complications.⁵⁷ In all other groups, PET was not cost-effective, and CT led to similar outcomes (in terms of quality-adjusted life-years) and to lower costs.

BIOPSY

If an SPN displays characteristics suggestive of malignancy, a tissue diagnosis should be obtained. In many cases, the appropriate form of tissue acquisition will be excisional biopsy by wedge resection, often followed by anatomic lung resection. Traditionally, excisional biopsy was performed, accepting the morbidity associated with thoracotomy. Especially for peripheral lesions, however, video-assisted thoracic surgery (VATS) has now supplanted thoracotomy as the procedure of choice. However, several alternative biopsy techniques may be performed in place of resection, including TTNB and bronchoscopy.

Transthoracic Needle Biopsy

Lesions that are between 1.0 and 3.0 cm in diameter should be considered for TTNB. The diagnostic yield of this procedure for SPNs is excellent, reaching 95% in some studies. The reported sensitivity ranges from 80 to 95% and the specificity ranges from 50 to 88%.^{58–60} A study of 222 patients who underwent TTNB for an SPN reported a positive predictive value of 98.6% and a negative predictive value of 96.6%⁶¹; however, several other studies reported false negative rates ranging from 3 to 29%.^{58,62} The complication rate associated with TTNB is relatively high—potentially as high as 30% and rarely lower than 10%, in even the most experienced hands.^{59,63} Most commonly, a pneumothorax results; however, chest tube placement is required only if the patient becomes symptomatic, a situation that occurs in approximately 50% of cases. In the absence of symptoms, observation with serial chest x-rays is generally appropriate. If no increase in the size of the pneumothorax is observed, the patient can be discharged with the expectation that the pneumothorax will resolve.

For lesions smaller than 1.0 cm, the risk-to-benefit ratio of TTNB rises to the point where other techniques are typically preferred. The utility of TTNB depends primarily on the characteristics of the SPN—in particular, its location. Nodules that are central or close to the diaphragm or the pericardium are less well suited to this technique than those at other sites.

Bronchoscopy

Bronchoscopy has a well-established role in the evaluation of central SPNs, which are amenable to direct visualization and biopsy. Most SPNs, however, are not central. Various adjunctive measures, including transbronchial needle biopsy and cytology brushings, are employed to improve the yield of bronchoscopy. For SPNs between 2.0 and 3.0 cm in diameter, the diagnostic yield of bronchoscopy ranges from 20 to

80%, depending on the size of the lesion, the incidence of malignancy in the study population, and the proximity of the lesion to the bronchial tree.^{64,65} For SPNs smaller than 1.5 cm, the yield drops to 10%.⁶⁶ Even though bronchoscopy has a low complication rate (about 5%), its low diagnostic yield for malignancy limits its utility in the evaluation of SPNs.

New technology has allowed the application of guidance techniques to the field of bronchoscopy. Ultrasound transducers affixed to the tip of a bronchoscope, endobronchial ultrasonography (EBUS), has become an important tool in mediastinal staging, with EBUS-transbronchial needle aspiration (EBUS-TBNA) sensitivities in the range of 92% and specificities of 98% reported.⁶⁷ Electromagnetic navigational bronchoscopy (ENB) uses three-dimensional CT reconstructions to provide guidance for bronchoscopic sampling of peripheral lesions. The diagnostic yield for peripheral lesions is in the range of 70%,⁶⁸ and experience within the community is growing. ENB is a technique that can provide tissue from central nodules as well as an alternative to TTNB or VATS for peripheral lesions, and offers the ability to place a fiducial marker for subsequent radiation therapy guidance.

Excisional Biopsy

The decision to proceed to excisional lung biopsy (open or VATS) must be carefully considered. The risk-to-benefit ratio of excisional biopsy for an individual patient is determined by clinical characteristics affecting perioperative morbidity and mortality, as well as by the expected risk of malignancy in the SPN.

Resection is the reference standard for tissue acquisition. The morbidity associated with VATS is less than that associated with thoracotomy; accordingly, when VATS lung biopsy is technically feasible, it is preferable to open lung biopsy. The overall morbidity is lower than 1% for VATS wedge resection, compared with 3 to 7% for the equivalent open procedure. Patients who have undergone VATS resection experience less pain, have shorter hospital stays, and recover sooner than those who have undergone open biopsy.^{69–71}

A technical consideration that must be contemplated when VATS is planned is possible conversion to thoracotomy. The conversion rate for VATS to thoracotomy has been reported to be as high as 33%, but there is evidence to suggest that this rate can be significantly reduced with careful patient selection and increasing experience in minimally invasive techniques.^{72,73} For example, modern experience with VATS techniques has demonstrated a low conversion rate of 2.5% in a series of 1,100 patients undergoing the more complex VATS lobectomy procedure.⁷⁴

Peripheral SPNs more than 1.0 cm in diameter are the lesions best suited to VATS excision. As SPNs become smaller and more central, they become harder to identify, and the rate of conversion to thoracotomy or the need to perform an anatomic resection increases. A wide variety of techniques have been employed to improve the identification of SPNs for VATS, ranging from dye staining through guide-wire localization. One of the more recent developments has been the use of technetium-labeled microalbumin combined with a gamma probe to successfully resect 96% of lesions using thoracoscopic techniques.⁷⁵ Despite demonstrated cost-effectiveness,⁷⁶ however, none of these techniques have

achieved wide acceptance, and most surgeons rely on digital palpation combined with radiographic guidance.

Differential Diagnosis

MALIGNANT LESIONS

Non–Small Cell Lung Cancer

As noted, NSCLC is the malignancy most frequently identified in an SPN. Most lung cancer patients are asymptomatic, and those who are symptomatic usually have advanced disease, including mediastinal lymph node involvement. Arterial invasion has also been shown to have an adverse effect on survival in patients with early-stage NSCLC.⁷⁷ The most common sites of metastases are the lymph nodes, the brain, the bones, and the adrenal glands. Accordingly, it is essential to perform a metastatic evaluation that focuses on these areas before proceeding with resection.

Adenocarcinoma and squamous cell carcinoma remain the most common types of NSCLC, but bronchoalveolar carcinoma is a well-differentiated subtype that has a prolonged doubling time. Because of its slow growth rate, it may be missed by PET scan.⁴⁹ Bronchoalveolar carcinoma may present as an SPN, particularly with a ground-glass appearance, as airspace disease, or as multiple nodules.

Small Cell Lung Cancer

Small cell carcinoma accounts for approximately 20% of lung cancers. Typically, it presents as a central mass in association with significant nodal disease, often accompanied by distant metastases.⁷⁸ Small cell carcinoma typically has a very short doubling time. Paraneoplastic syndromes are more common with small cell lung cancer than with NSCLC.

Pulmonary Carcinoid Tumor

Pulmonary carcinoid tumors are uncommon neuroendocrine neoplasms that account for 1 to 2% of lung cancers.⁷⁹ They are classified as either typical or atypical, depending on their histology, but represent a spectrum of neuroendocrine tumors.⁸⁰ Either type of carcinoid may present as an SPN, usually in the fifth or sixth decade of life. Typical carcinoid tumors have a very long doubling time—up to 80 months—and thus may be mistaken for benign lesions.⁸¹ Atypical carcinoid tumors have a much shorter doubling time and are more likely to show an increase in size on serial CT scans. Typical carcinoid tumors have an extremely low incidence of recurrence and are not usually associated with nodal metastasis.

Metastatic Malignancies

Metastases to the lung frequently appear as smooth, round, well-demarcated lesions. They often are multiple, tend to be found in the better vascularized lower lung zones, and rarely are associated with mediastinal adenopathy. Most pulmonary metastases derive from the lungs, the colon, the testicles, the breasts, melanomas, or sarcomas. Treatment tends to be palliative, based on the diagnosis of the primary tumor, but it may be curative in cases of metastatic sarcoma or testicular carcinoma. In patients with these cancers, limited wedge resection of a metastasis to the lung has been shown to confer a survival advantage; this measure may also be beneficial for

patients with metastatic head and neck cancer and, occasionally, for those with metastatic melanoma.⁸² Recent reports with modern chemotherapeutic strategies and resection have suggested that prolonged survival is possible in colorectal cancer metastatic to the lung, with 5-year survival of 67%.⁸³ Improved outcomes are thought to be more likely in colorectal cancer patients with less than two pulmonary metastases.⁸⁴

BENIGN LESIONS

Pulmonary Hamartoma

Pulmonary hamartomas are the most common benign pulmonary tumors and the third most common cause of SPNs overall. Most (90%) arise in the periphery of the lung, but endobronchial hamartomas are seen as well. Because they are most common in the periphery, hamartomas are usually asymptomatic. When a potential hamartoma appears as an SPN on a chest x-ray, CT scanning is warranted for further evaluation.

Certain typical CT findings suggest that the SPN is likely to be a hamartoma. One such finding is a particular pattern of calcification. Calcification is more common in benign lesions than in malignant tumors. Four patterns of calcification are considered benign: central, diffuse, laminated, and “popcornlike.” The first three patterns are most commonly associated with an infectious condition (e.g., histoplasmosis or tuberculosis). The popcornlike pattern, however, indicates that the lesion is probably a hamartoma. Unfortunately, calcification is present in only about 50% of benign lesions, and only about 50% of hamartomas are calcified.³¹ It is important to remember that pulmonary carcinoid tumors and metastases to the lung (especially those from osteosarcomas, chondrosarcomas, or synovial cell sarcomas) may also have calcifications. Another reliable marker of a hamartoma is the finding of fat within the lesion on a CT scan; however, fewer than 50% of hamartomas demonstrate this characteristic. PET scanning, particularly the correlation between PET and CT findings on PET-CT, has been suggested as a useful diagnostic tool.⁸⁵

Inflammatory Nodules

Sarcoidosis is known as the great mimicker, but it rarely presents as an SPN.⁸⁶ Most commonly, it presents as hilar and mediastinal lymphadenopathy and diffuse parenchymal involvement. When it does present as an SPN, it is almost invariably a solid lesion, hardly ever a cavitary one. The incidence of sarcoidosis is highest in African-American women between 20 and 40 years of age. If sarcoidosis is suspected during the evaluation of an SPN, an elevated angiotensin-converting enzyme level supports the diagnosis, but a normal level does not exclude it. If a biopsy is performed, the presence of noncaseating granulomas on pathologic evaluation helps establish the diagnosis. If a diagnosis of sarcoidosis is suspected, PET scanning has been suggested as an effective method to identify extrathoracic sites of disease to target for pathologic confirmation.⁸⁷

Pulmonary rheumatoid nodules are present in fewer than 1% of patients with rheumatoid arthritis.⁸⁸ They are usually associated with rheumatoid nodules in other parts of the body but may precede any systemic manifestations of the

disease. Pulmonary rheumatoid nodules, although generally asymptomatic in themselves, arise from underlying rheumatoid activity. When the underlying disease is active, the nodules may grow, simulating malignancy. An elevated serum rheumatoid factor level is typical and helps confirm the diagnosis.

Wegener granulomatosis is a necrotizing vasculitis that affects both the upper and the lower respiratory tract, as well as the kidneys. It presents with an SPN in approximately 20% of patients.⁸⁹ If vasculitis is suspected during evaluation of an SPN, laboratory studies should include testing for cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA); a positive result on this test is highly suggestive of Wegener granulomatosis. Treatment includes the cytotoxic drug cyclophosphamide, either alone or in combination with corticosteroids.

Infectious Nodules

An SPN can also represent an infectious granuloma caused by tuberculosis, atypical mycobacterial diseases, histoplasmosis, coccidioidomycosis, or aspergillosis. Such granulomas frequently have a cavitary appearance on CT scans. Occasionally, a chest x-ray taken with the patient in different positions shows shifting of the position of the cavity's contents or a crescent of air around the mass (the Monod sign).⁹⁰ This radiographic finding is characteristic of a mycetoma, usually aspergilloma. Depending on the circumstances—in particular, on whether there has been significant hemoptysis and whether pulmonary function is reasonably well preserved—many of these lesions are best treated with resection. Others are best diagnosed by noninvasive techniques and treated with antimicrobial therapy.

Pulmonary dirofilariasis is a rare but well-attested cause of SPNs that is the consequence of infestation of human lungs by the canine heartworm *Dirofilaria immitis*. This organism is transmitted to humans in larval form by mosquitoes that have ingested blood from affected dogs.⁹¹ Because humans are not suitable hosts for this organism, the larvae die and embolize to the lungs, where they initiate a granulomatous response. Typically, these lesions are pleura based, and the diagnosis is made at the time of resection.⁹² Once the diagnosis is made, no further therapy is required.

Echinococcosis is a hydatid disease caused by the tapeworm *Echinococcus granulosus*. It is endemic to certain areas of the world where sheep and cattle are raised. Normally, it is ingested incidentally; the parasite penetrates the bowel wall and travels to the lungs in 10 to 30% of cases.^{93,94} A complete blood count usually demonstrates peripheral eosinophilia. If echinococcosis is suspected, a hemagglutination test, which has a sensitivity of 66 to 100% and a specificity of 98 to 99% for *Echinococcus*, should be performed. TTNB should not be performed because there is a risk that cyst rupture triggers an anaphylactic reaction to the highly antigenic contents. Patients may be treated with anthelmintic agents, but the incidence of persistent or recurrent disease is high. Accordingly, surgical resection should be considered.

OTHER CONSIDERATIONS

Pulmonary amyloidosis may present in either a diffuse or a nodular form. The prognosis is most favorable when it presents as an asymptomatic SPN. Typically, the nodule is well defined and between 2 and 4 cm in diameter. Unless the

patient exhibits systemic manifestations of amyloidosis, the diagnosis can be confirmed only by biopsy of the nodule.⁴²

Rounded atelectasis usually presents as a pleura-based nodular density that occurs secondary to pleural scarring and thickening. An effort should be made to look for associated pleural plaques resulting from asbestos exposure. The CT scan usually demonstrates an SPN with a “comet tail.” Biopsy is not required unless mesothelioma is strongly suspected or the SPN is seen to have grown on successive CT scans.

Management

The ACCP attempted to provide evidence-based guidelines to direct the evaluation of patients with SPNs 8 to 10 mm in diameter in their 2007 consensus statement.³⁹ Unfortunately, few, if any, randomized controlled trials exist to direct management. Most clinicians rely on a combination of single-institution studies, a few prospective trials, and clinical acumen to assess a given patient's risk profile to inform decisions on invasive and noninvasive testing. The initial step in decision making is to confirm that the lesion is, in fact, new, and to compare current chest x-rays or CT scans with any previous images that are available. An SPN whose size has been stable for 2 years on diagnostic images will be benign 90 to 95% of the time. If no previous images are available for comparison, the patient should undergo a clinical evaluation to determine their risk profile. This evaluation must be individualized according to the characteristics of the patient and the lesion. On the basis of the patient's age, exposure and smoking history, the size of the SPN, and the characteristics of the lesion's borders, an SPN for which no previous diagnostic images are available can be initially classified as having a low, intermediate, or high probability of cancer [see Table 3].^{7,95,96} This classification governs the subsequent workup. Whereas a patient with a high-probability SPN needs a complete evaluation progressing toward resection with minimal delay, the same strategy would not be cost-effective for a patient with a low-probability SPN. It is important not to subject a patient with a high-probability SPN to studies that will not change clinical management or outcome: doing so will delay diagnosis and treatment unnecessarily.

At this point in the evaluation, if the nature of the SPN is still indeterminate and the lesion is larger than 1 cm, there may be a role for PET or PET-CT scanning. If PET scanning yields negative results, the SPN is likely benign, and follow-up CT scanning is appropriate. If PET scanning yields positive results and the patient is at high surgical risk, TTNB, bronchoscopy, or guided bronchoscopy may be performed to

Table 3 Initial Assessment of Probability of Cancer in Solitary Pulmonary Nodule

Characteristics of Patient or Lesion	Probability of Cancer		
	Low	Intermediate	High
Patient age (yr)	< 40	40–60	> 60
Patient smoking history	Never smoked	< 20 pack-yr	≥ 20 pack-yr
Lesion size (cm)	< 1.0	1.1–2.2	≥ 2.3
Lesion margin	Smooth	Scalloped	Spiculated

establish a diagnosis. If, however, the patient is at reasonable surgical risk, proceeding directly to VATS resection (and, potentially, to lobectomy) offers the best chance of cure for a probable carcinoma.

For patients with SPNs smaller than 1.0 cm, the optimal approach may be to perform serial CT scanning at an initial 3-month interval for a minimum of 2 years. The rationale for this approach is based on the difficulty of identifying these lesions with VATS, the low likelihood of establishing a diagnosis with TTNB, and the possibility that the lesion may

be benign. If the lesion has grown visibly between scans, it is probably malignant, and proceeding with resection for diagnosis and treatment is appropriate. The likelihood that nodal metastases will develop in a closely followed SPN smaller than 1.0 cm is low.⁷³ If the SPN proves to be malignant, scanning at 3-month intervals is unlikely to alter the eventual outcome. Society guidelines continue to be refined in an effort to provide helpful recommendations.

Financial Disclosures: None Reported.

6 PARALYZED DIAPHRAGM

Matthew O. Hubbard, MD, Raymond P. Onders, MD, FACS, and Philip A. Linden, MD, FACS*

Diaphragmatic dysfunction may be unilateral or bilateral, with symptoms ranging from dyspnea only on extreme exertion to ventilator dependence. The etiology, treatment, and prognosis are quite different in unilateral and bilateral paralysis. A paralyzed hemidiaphragm may occur in isolation or as part of a systemic disease, whereas bilateral diaphragmatic paralysis usually occurs as result of a traumatic or neuromuscular degenerative process. The symptoms related to a paralyzed diaphragm are explained by both the loss of muscular action of the diaphragm in respiration and the loss of anatomic domain between the thorax and abdomen.

Unilateral dysfunction usually results from transection, bruising, stretching, or manipulation of one of the phrenic nerves. A paralyzed hemidiaphragm may restrict a patient's vital capacity by almost 20% in a seated position and up to 40% in a supine position. Compression of the lower lobe of the lung may result in ventilation-perfusion mismatch. A small but significant reduction in the arterial oxygenation may be seen, although hypercarbia is usually not present.¹ These alterations are usually well tolerated in a young, healthy patient, with the sole symptom being dyspnea on exertion. A patient at the extremes of life (early childhood or late adulthood) or suffering from underlying lung diseases, obesity, or other systemic disorders may be more adversely affected by unilateral diaphragmatic paralysis.

Bilateral dysfunction may be attributable to central nervous system disorders (central hypoventilation resulting in diminished central triggering of the diaphragms), diffuse nerve dysfunction (disorders such as amyotrophic lateral sclerosis [ALS]), or spinal cord injury (SCI) above C5. Bilateral paralysis causes more severe respiratory symptoms than unilateral paralysis. Vital capacity can be reduced 45 to 50% from predicted in patients with bilateral paralysis.² Arterial hypoxemia can be seen as a result of ventilation-perfusion mismatches at the lung bases, and hypercarbia may result from a decrease in tidal volume and minute ventilation. Assisted ventilation (either noninvasive or invasive) is usually required.

Clinical Evaluation

HISTORY

In adults with a paralyzed hemidiaphragm, the most common complaint is typically dyspnea on exertion. Often there are no symptoms at rest.

Bilateral diaphragmatic paralysis results in more severe symptoms than unilateral paralysis, resulting in profound respiratory compromise. Patients depend on accessory

muscles of inspiration more, may experience dyspnea in the supine position and related sleep disturbances with daytime fatigue, and may suffer from chronic respiratory failure.

Infants and young children depend on the diaphragm to achieve adequate vital capacities because they have a more compliant chest wall, weaker accessory muscles of respiration, and a more mobile mediastinum than adults. Unilateral paralysis may cause severe respiratory compromise requiring mechanical ventilation; bilateral diaphragmatic paralysis almost always requires prompt ventilator support.

COMMON CAUSES OF DIAPHRAGMATIC PARALYSIS

The most common causes of diaphragmatic paralysis are listed in Table 1. The most common causes of unilateral paralysis are neoplastic invasion, idiopathic, and iatrogenic.

Malignancies account for roughly one third of cases of diaphragm paralysis. Neoplasms of bronchogenic origin are most common, although malignancies of the mediastinum, including thymomas, lymphomas, and germ cell tumors, can also result in interruption of the phrenic nerve input to the diaphragm. The phrenic nerve can be damaged by either direct mediastinal invasion of a tumor or metastasis of a tumor to the mediastinal lymph nodes with subsequent lymph node enlargement. Overall, only about 10% of patients with unexplained diaphragmatic paralysis will regain function of the diaphragm.³

Phrenic nerve damage can occur during thoracic and cervical surgery as well as during cervical vein catheter insertion and has even been described as a result of cervical chiropractic manipulation. Injury to the phrenic nerve during cardiac surgery has fallen dramatically with the transition from topical ice slushes to cooling jackets but still may occur as a result of stretching, compression, or sectioning. The use of cautery during high dissection of the internal mammary artery near the first rib may also injure the nerve. Patients with an elevated hemidiaphragm on chest radiographs at the time of discharge after cardiac surgery have a 20% chance at 1 year

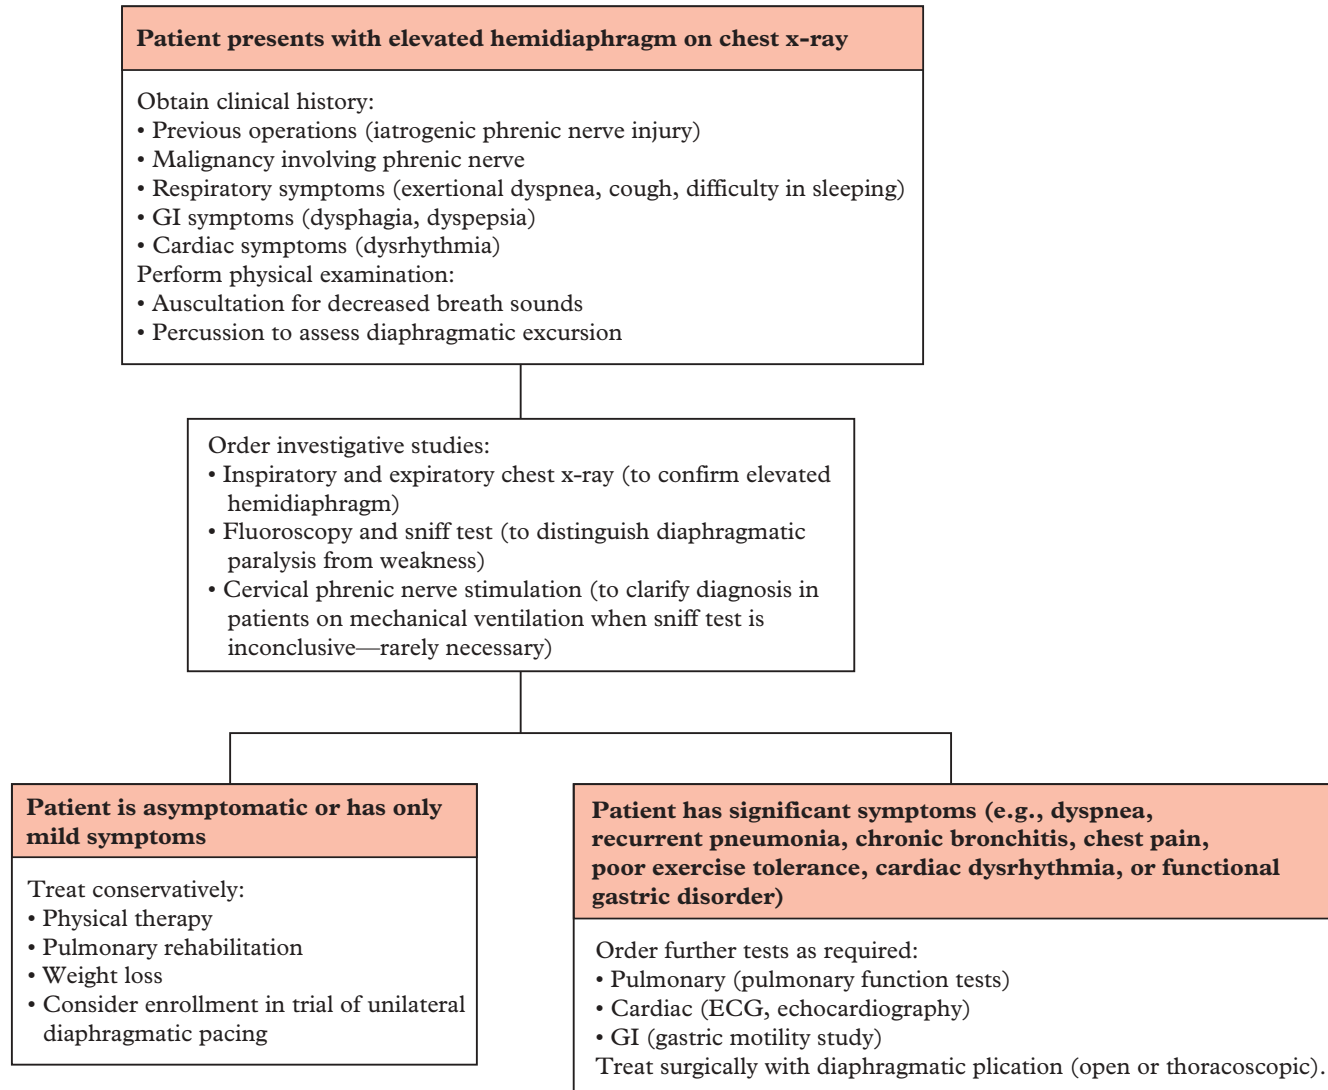

Table 1 General Causes of Unilateral and Bilateral Diaphragmatic Paralysis

Neoplasm invasion
Phrenic nerve injury: surgical section or stretching, cooling, chiropractic cervical manipulation, cervical venipuncture, birth trauma, cervical disk surgery, blunt or penetrating chest trauma
Neuritis: brachial neuritis, herpes zoster infection, mononeuritis multiplex, paraneoplastic neuritis
CNS or spinal cord disorders: neuralgic amyotrophy, stroke, multiple sclerosis, rhizotomy, infantile spinomuscular atrophy, Arnold-Chiari malformation, syringomyelia
Nerve compression: cervical spondylosis, mediastinal lymph node enlargement, substernal goiter
Miscellaneous: diabetes mellitus, carbon monoxide poisoning, upper abdominal surgery, liver transplantation

CNS = central nervous system.

* The authors and editors gratefully acknowledge the contributions of the previous authors, Bryan F. Mayers, MD, FACS, and Benjamin D. Kozower, MD, to the development and writing of this chapter.

Evaluation of Elevated Hemidiaphragm

of continued diaphragmatic dysfunction. Injury can occur during dissection of mediastinal vessels during lobectomy. Typically, this is more common on the right than the left (the phrenic nerve courses closer to the hilum on the right than on the left) and may be more commonly injured after upper lobectomies than lower (the nerve courses closer to the superior pulmonary vein than the inferior vein). The phrenic nerve is at risk during a supraclavicular (or scalene) lymph node biopsy as it courses directly anterior to the anterior scalene muscle. The phrenic nerve is also at risk during thymectomy as perithymic tissue often extends bilaterally near both phrenic nerves. If one nerve is invaded by a thymoma, it should be resected en bloc with the thymoma provided that the other nerve is healthy and can be spared. Cautery should generally be avoided within 1 cm of the phrenic nerve. Typically, morbidity surrounding injuries to the phrenic nerves is minimal. Exceptions to this, however, are in pediatric patients undergoing open heart surgery, patients post-lung transplantation, and those adult patients with preexisting respiratory compromise. This may result in a failure to wean from mechanical ventilation after surgery.

PHYSICAL EXAMINATION

At rest, adult patients with a paralyzed diaphragm may appear asymptomatic or have the nonspecific complaints discussed above. On physical examination, diminished breath sounds are heard on the affected base, with decreased excursion of the diaphragm noted on percussion. Paradoxical inward motion of the ipsilateral abdominal wall may also be seen.⁴

A patient with bilateral diaphragmatic paralysis is much more likely to become symptomatic, complaining of the symptoms above, and is also subject to the neurologic or neuromuscular complaints related to the underlying etiology. Physical examination almost always reveals significant use of accessory inspiratory muscle use. Tachycardia and tachypnea are usually present. Characteristically, paradoxical inward movement of the abdominal wall is seen with inspiration.⁴

Investigative Studies

Diaphragmatic paralysis is usually discovered following an inspiratory chest radiograph, which may demonstrate an elevated diaphragmatic dome with sharpened and deepened costovertebral and costophrenic sulci [see Figure 1]. With left-sided paralysis, the stomach may rotate with the greater curvature facing cephalad and showing two fluid levels corresponding to the inverted fundus and body.⁴

Fluoroscopy or ultrasonography can be used for functional evaluation of the diaphragm in patients with suspected paralysis. Elevation of the diaphragm above the normal range, paradoxical movement with inspiration (especially while sniffing, the “sniff test”), and a mediastinal swing during respiration may all be seen. All of these findings may also be seen in other respiratory ailments and require a good deal of judgment to evaluate. The “sniff test,” rapidly inhaling with a closed mouth, should show a paradoxical upward motion of the diaphragm of at least 2 cm to be considered a positive test

Figure 1 Chest radiograph showing left diaphragmatic paralysis in a breast cancer patient with malignant adenopathy involving the left phrenic nerve near the left main pulmonary artery.

for paralysis. This test may be unobtainable in patients with severe weakness or on mechanical ventilation.⁵

Ultrasound evaluation can also be used to evaluate suspected diaphragmatic paralysis and may be slightly more sensitive than fluoroscopy.⁶ Using ultrasonography, a paralyzed diaphragm fails to increase in thickness during inspiration compared with a normally functioning diaphragm. This was seen in single patients comparing paralytic hemidiaphragms with the contralateral leaflets and also comparing experimental and control patients. Rarely, equivocal noninvasive testing may be augmented with phrenic nerve stimulation with electromyographic measurement of nerve latency; this may be helpful with patients being supported by mechanical ventilation.⁷

Management

CONSERVATIVE VERSUS SURGICAL TREATMENT

Surgical treatment of diaphragmatic paralysis should be reserved for patients with moderate to severe symptoms of respiratory compromise. Adult patients with mild symptoms, such as dyspnea on exertion, would benefit from conservative treatment focusing on physical therapy, pulmonary rehabilitation, and weight loss.

The standard treatment of diaphragmatic paralysis is plication of the affected diaphragm, first performed by Bisgard in 1947 to treat congenital eventration of the diaphragm in an infant with respiratory distress. Several descriptions of plication of the diaphragm exist in the literature for diaphragmatic

paralysis and eventration, varying in suture placement and surgical approach. Developments in phrenic nerve repair and diaphragm plication (DP) have emerged in recent years.

PLICATION OF THE DIAPHRAGM

A posterolateral incision at the seventh or eighth intercostal space provides access to the thoracic cavity for a plication procedure. Four to six parallel rows of nonabsorbable suture with pledgets should be placed in an anteroposterior orientation within the central tendon of the diaphragm. Ideally, these sutures should not strike the phrenic vessels and nerve branches. The phrenic vessels often course under the diaphragm and are not visible from above [see *Figure 2*].

Thoracoscopic approaches to diaphragmatic plication have been described. One study of 25 patients undergoing video-assisted thoracoscopic diaphragm plication showed that forced vital capacity (FVC), forced expiratory volume at 1 second (FEV₁), functional residual capacity (FRC), and total lung capacity (TLC) improved by 17%, 21.4%, 20.3%, and 16.1%, respectively, at 6 months.⁸ Symptomatic dyspnea also improved, and 17 patients were able to return to work.

Radial plication of the muscular portion of the diaphragm, avoiding the mediastinal pleura, has been described through

a transabdominal and transthoracic approach.⁹ This procedure allows for protection of the phrenic nerve branches and vessels. This has also been described through a thoracoscopic approach in children and adults: a three-port technique using anterior and posterior thoracic ports at the sixth and eighth interspaces, respectively, for plication, and a subcostal port used for grasping and displacing the central tendon of the diaphragm through the abdomen.¹⁰

A study of plication in 17 patients (16 men, one woman), with an average age of 54 years, showed subjective improvement in dyspnea score, as well as objective improvement in FVC, TLC, and FRC, as well as arterial oxygenation, at 6 months.¹¹ These results were maintained in the six patients who were followed for more than 5 years. A different study of 15 patients with a mean follow-up of 10 years after plication showed continued improvement in FVC, FEV₁, FRC, and TLC by 11.8%, 15.4%, 26%, and 13.3%, respectively.¹²

Infants and children who suffer from diaphragmatic paralysis are much more susceptible to respiratory compromise. These children are much more likely to require mechanical ventilation and to be exposed to the complications therein. Diaphragmatic plication has been shown to be an effective means to wean children from mechanical ventilation.¹³

Figure 2 Several parallel rows of sutures are placed in the muscular portion and central tendon of the diaphragm and tied with the aid of a knot pusher. A pledget should be placed at the ends of the suture if the diaphragm is thinned.

REPAIR OF PHRENIC NERVE INJURY

Some cases of diaphragmatic paralysis result from traumatic or iatrogenic severing of the phrenic nerve. Case reports of direct repair of the phrenic nerve using microsurgery techniques have been described in adults and children by end-to-end anastomosis and sural nerve graft techniques; an improvement in diaphragmatic function occurred as early as 6 months after surgery.¹⁴ Repair of the phrenic nerve can be performed for simple transection, whereas sural nerve grafting is used for replacement of phrenic nerve segments that were resected en bloc with tumor. There are no reports of nerve repair in large numbers of patients.

DIAPHRAGMATIC PACING

Indications for Diaphragm Pacing

Direct phrenic nerve pacing and intramuscular DP systems were designed to replace or delay the need for patients requiring long-term positive pressure mechanical ventilation via tracheostomies. In the 1980s, Mortimer and colleagues showed that the diaphragm could be directly stimulated at the motor point (area of phrenic nerve insertion) of the diaphragm to provide ventilation.¹⁵

The initial clinical indications for phrenic nerve or DP have been cervical SCIs and congenital central hypoventilation syndromes. SCI involves the disruption of the signal pathway from the respiratory center in the brain to the respiratory nerves (primarily the phrenic nerves), whereas central hypoventilation syndromes generally involve a decreased respiratory drive. Central hypoventilation is a rare diagnosis, affecting one in 50,000 live births; these children require permanent nighttime positive pressure ventilation unless phrenic nerve pacing is possible.

Of 11,000 new SCIs each year in the United States, slightly more than half are affected by quadriplegia, with only 4% requiring long-term mechanical ventilation. In a prospective worldwide trial of DP in this group, 50 patients were implanted.¹⁶ The average age was 36 years (range 18 to 74 years), and the time from injury to implantation was 5.6 years (range 0.3 to 27 years). Ninety-eight percent of the patients had DP-stimulated tidal volumes above 5 to 7 cc/kg for 4 or more continuous hours, with 50% using DP for continuous 24-hour ventilation. Age and time from injury directly affect the conditioning time needed to achieve independent ventilation, with younger and more recently injured patients weaning from the ventilator faster.¹⁷ In a long-term analysis of 24 patients, 60% reported fewer secretions, and 95% reported greater freedom and independence. This multicenter trial led to approval by the Food and Drug Administration in June 2008.

DP is used in patients with ALS (Lou Gehrig disease), where respiratory insufficiency is the major cause of mortality. There is a significant risk of impending respiratory failure and death when FVC falls below 25 to 30%.¹⁸ In this group of patients, the goal is to delay the need for mechanical ventilation by implanting the DP and stimulating the muscle to maintain diaphragm strength prior to end-stage weakness.

The results of a multicenter prospective trial comparing noninvasive ventilation with DP combined with noninvasive

ventilation in 145 subjects with ALS showed a decreased respiratory decline and improved survival with pacing.¹⁹ After conditioning the diaphragm with the DP, the rate of decline in FVC fell from 2.62% per month to 1.25% per month. Respiratory compliance increased 18% from improving posterior lobe ventilation.

The use of DP for the treatment of ventilator dependence following iatrogenic diaphragmatic paralysis is currently under sporadic investigation

Surgical Technique of Laparoscopic Diaphragm Pacing

For DP to be effective, the phrenic nerve must be intact and able to provide intramuscular conduction pathways. Unfortunately, many patients with tetraplegia have sustained injury to the phrenic motor neurons in the spinal cord and/or phrenic rootlets. Prior to implantation, an assessment of phrenic nerve function should be performed. In patients with ALS or central hypoventilation, fluoroscopy of the diaphragm can also be done to see that volitional diaphragm movement is intact, commonly referred to as a sniff test.

Paralytic agents cannot be used during the pacer insertion procedure as the diaphragm has to be stimulated during the operation. The surgery is described in four phases: exposure, mapping, implantation, and routing. The exposure consists of the setup for the standard laparoscopy with the initial port supraumbilical for adequate visualization of the diaphragm. Two lateral subcostal 5 mm ports are placed for the mapping probe for each side, and these are used initially to completely divide the falciform ligament, which allows easier visualization of the medial aspect of the right diaphragm and easier exit of the pacing electrodes through a 12 mm epigastric port. The epigastric port is used for the diaphragm implant instrument.

Mapping involves finding the point on the abdominal side of the diaphragm where stimulation causes the greatest diaphragm excursion. The mapping instrument has flexible tubing inside a rigid cannula that connects to the operating room suction. The working part of the mapping instrument has a circular electrode that can be stimulated when temporarily attached to the diaphragm by the suction [see Figure 3]. Stimulation is applied in either a twitch or burst mode from the clinical station through a connecting cable. Mapping allows qualitative and quantitative data to be obtained. Quantitatively, changes in abdominal pressures are measured. Qualitatively, observation of the diaphragm contraction is performed. The stronger the stimulated contraction, the closer the mapping probe is to the motor point of the diaphragm. The primary electrode site is identified at the location of maximal pressure change in each hemidiaphragm. A secondary electrode site is identified as either a backup to the primary site or at a location in each hemidiaphragm that recruits another region (e.g., anterior, lateral, or posterior) of the diaphragm at a similar magnitude. On the right diaphragm, the motor point is just lateral to the central tendon, and on the left diaphragm, the motor point tends to be much more lateral because the phrenic nerve travels on the lateral aspect of the pericardium and enters the diaphragm more laterally.

Once the primary and secondary electrode sites are identified in each hemidiaphragm, the implantation phase begins.

Figure 3 A laparoscopic mapping probe is being held onto the left diaphragm with suction and receives electrical stimuli from an external clinical station. The blue marks were placed at the locations of the strongest contractions.

An intramuscular electrode is introduced into the abdominal cavity with the electrode delivery instrument. The implant instrument needle is inserted into the diaphragm at an angle so that the electrode lead travels parallel to the plane of the diaphragm prior to exit, and the delivery instrument is withdrawn [see Figure 4]. The electrode is then tested to ensure that the desired response to twitch stimuli is achieved, and if the response is not adequate, the electrode may be withdrawn and another implanted. Once all four electrodes are implanted, they are brought out through the epigastric port, keeping the right and left sides separated. Excess electrode length is kept in the abdomen on top of the liver. The

Figure 4 The electrode implant device houses the electrode in the needle and is placed into the diaphragm tangentially. Countertraction can be applied by a second instrument to help deploy the electrode, which has a small barb on the end of it.

electrodes will be tunneled subcutaneously to an area in the upper chest or abdomen at a site deemed appropriate by the surgeon and patient's caregivers. An additional indifferent electrode will be placed subcutaneously through a separate percutaneous exit site.

Electrode evaluation is performed by adjusting individual stimulus parameters (amplitude, pulse width, rate, and frequency) so that a comfortable level of stimulation can be identified for the diaphragm conditioning sessions. The DP system will be set to provide a tidal volume that provides 15% above the basal needs (5 to 7 cc/kg) and that the patient can easily tolerate. For SCI patients and for ALS patients, the highest setting that causes no discomfort will be used.

ALS patients begin conditioning by pacing five 30-minute sessions a day. Continuous positive airway pressure (CPAP) or noninvasive ventilation may still be needed to maintain an upper airway and can be used in conjunction with the DP system. A weaning program for SCI patients is begun where the DP unit is turned on and the ventilator is turned off. The patients are placed back on the ventilator when they feel uncomfortable or if their tidal volumes start dropping because of diaphragm fatigue. Initially, patients may tolerate only 15 minutes of DP. If the DP system is implanted early after an SCI, the patient can be rapidly transitioned from the mechanical ventilator to DP. Figure 5 shows the system attached to a pediatric patient for whom weaning will be started the day of surgery. The diaphragm can recover quite rapidly from training, so patients and their caregivers can repeat a session every hour. The length of time it takes to go more than 4 continuous hours depends on the amount of time the patient and caregivers devote to this process.

The future application for temporary use in the intensive care unit (ICU) has some excellent theoretical possibilities, but well-designed trials will need to be done to identify the actual role of DP in the ICU.

Financial Disclosures: Dr. Raymond P. Onders has received research grants from Synapse Biomedical Inc, Oberlin, OH.

Figure 5 The diaphragm pacing system has already been programmed for conditioning and is attached via percutaneously placed diaphragm electrodes in this spinal cord-injured child for early conditioning and weaning from the ventilator.

7 OPEN ESOPHAGEAL PROCEDURES

Cameron D. Wright, MD, FACS

The remarkable developments in diagnosis, imaging, and surgical treatment of esophageal diseases over the past 15 years have resulted in markedly better patient outcomes, and the morbidity and mortality associated with surgery of the esophagus have been substantially reduced. In particular, the operative techniques employed to treat esophageal disease have advanced considerably as a result of the successful introduction of minimally invasive approaches to the esophagus. For a number of diseases (e.g., achalasia and routine antireflux surgery), minimally invasive procedures have proved to be as effective as their open counterparts while causing less postoperative morbidity. The growing stature of minimally invasive approaches does not, however, diminish the importance of the equivalent open approaches. In this chapter, we describe common open operations performed to excise Zenker diverticulum, to manage complex gastroesophageal reflux disease (GERD), and to resect esophageal and proximal gastric tumors.

General Preoperative Considerations

METHODS OF PATIENT ASSESSMENT

The functional results achieved with esophageal procedures become more predictable when the approach to preoperative patient evaluation is precise and reproducible. The ciné barium swallow remains the most cost-effective method for initial evaluation of esophageal anatomy and function. It should be employed before endoscopy because the results may direct the endoscopist's attention to particular areas of concern. In addition, endoscopic examination alone is often insufficient for assessing esophageal motility disorders or defining the complex anatomy of a paraesophageal hiatal hernia.

Endoscopic ultrasonography (EUS) is an extension of the visual mucosal examination. The information it can provide about the extension of mass lesions beyond the confines of the esophageal wall is helpful in planning surgical resection. In addition, EUS can differentiate benign stromal tumors from cystic or malignant neoplasms on the basis of characteristic echogenicity patterns. EUS-FNA (fine-needle aspiration) is used to confirm suspected nodal metastases seen during the EUS examination. The combination of EUS and computed tomography (CT) permits highly precise anatomic assessment of esophageal neoplasms, definition of the extent of local invasion, and identification of regional metastases.

Functional imaging with photodynamic or vital staining allows accurate diagnosis of dysplastic or malignant mucosal lesions in their earliest stages. Positron emission tomography (PET) yields similar results by localizing metabolically active tissue regionally or at distant sites. The combination of morphologic data from high-resolution CT and functional data from PET is particularly effective for identifying

occult metastases that would preclude curative resection for esophageal cancer.

Esophageal manometry, 24-hour esophageal pH testing, and nuclear studies for assessment of esophageal and gastric transit provide functional data that can facilitate the diagnosis and treatment of GERD, achalasia, and other disorders of the esophagus. They are useful complements to standard investigations (e.g., ciné barium swallow and endoscopy).

Complete preoperative investigation of all patients, even those with classic histories and physical findings, is mandatory. The data from anatomic and functional testing allow the surgeon to plan the operation more appropriately and effectively (e.g., deciding on the need for esophageal lengthening in patients with paraesophageal hernias or choosing between a complete and a partial fundoplication in patients with hernias associated with varying degrees of esophageal dysmotility).

OPTIMIZATION OF PATIENT HEALTH STATUS

Patients with obstructing esophageal diseases are often elderly, debilitated, and malnourished. Although months of insufficient nutrition cannot be corrected in the space of a few hours, anemia, dehydration, and electrolyte abnormalities can be mitigated by means of intravenous support and appropriate laboratory monitoring. If esophageal obstruction prevents oral intake, endoscopic dilation of the stricture, accompanied by either nasogastric intubation or percutaneous endoscopic gastrostomy (PEG), is often indicated; the patient should then be able to resume at least a liquid diet. Caution should be used when addressing esophageal obstruction in preoperative patients before induction therapy is given. Most surgeons prefer not to have a PEG tube placed in the stomach for fear of compromising its blood supply when an esophagectomy is planned. Alternative options include a nasogastric tube, a jejunostomy tube, or total parenteral nutrition. If weight loss has exceeded 10%, enteral nutrition, comprising at least 2,000 kcal/day of a high-protein liquid diet, should be administered for at least 10 days before the operation. Cardiovascular, renal, hepatic, and respiratory function should be documented and optimized. If the patient is aspirating, the esophagus should be evacuated and the patient should be given nothing by mouth until after the operation. Aspiration pneumonia should always be corrected preoperatively.

Cricopharyngeal Myotomy and Excision of Zenker Diverticulum

PREOPERATIVE EVALUATION

Patients who are candidates for cricopharyngeal myotomy usually present with difficulty initiating swallowing, cervical dysphagia, and a history of pulmonary aspiration. These

symptoms of cricopharyngeal dysfunction may or may not be associated with a Zenker diverticulum. Ciné contrast studies may reveal poor pharyngeal contractility, pulmonary or nasal aspiration, abnormalities of the upper esophageal sphincter, pharyngeal pouches, or other structural abnormalities in the distal esophagus. Barium is the usual contrast agent as it is inert if aspirated.

Zenker diverticulum is a pulsion diverticulum that arises adjacent to the inferior pharyngeal constrictor, between the oblique fibers of the posterior pharyngeal constrictors and the cricopharyngeus muscle. This mucosal outpouching results from a transient incomplete opening of the upper esophageal sphincter. The diverticulum ultimately enlarges, drapes over the cricopharyngeus, and dissects behind the esophagus into the prevertebral space. The pouch usually deviates to one side or the other; accordingly, the side on which the deviation occurs must be determined by means of a barium swallow so that the appropriate operative approach can be selected. Esophageal motility studies (not usually performed) may show either incomplete upper esophageal relaxation on swallowing or poor coordination of the upper esophageal relaxation phase with pharyngeal contractions. Upper gastrointestinal (GI) endoscopy is performed preoperatively to exclude the presence of a pharyngeal or esophageal carcinoma and to assess the upper GI anatomy. If there is evidence of GERD, proton pump inhibitors (PPIs) are given.

In symptomatic patients (e.g., those with dysphagia, nocturnal cough, or recurrent pneumonia from aspiration), surgical therapy is indicated regardless of whether a pouch is present or how large it may be. Such treatment involves correcting the underlying cricopharyngeal muscle dysfunction with a cricopharyngeal myotomy. If there is a diverticulum larger than 2 cm, it should be excised in addition to the cricopharyngeal myotomy. Alternatively, the diverticulum may be managed via endoscopic obliteration of the common wall between the pharyngeal pouch and the esophagus with either a stapler or a laser. Cricopharyngeal incoordination may be temporarily relieved by injecting botulinum toxin into the cricopharyngeus.

OPERATIVE PLANNING

The patient is placed on a clear fluid diet for 2 days before the operation. With the patient under general anesthesia, the trachea is intubated with a single-lumen endotracheal tube. Cricoid pressure is applied to prevent aspiration of diverticular contents. A soft roll is placed behind the shoulders to extend the neck. The patient is placed in a 20° reverse Trendelenburg position, and the legs are wrapped with pneumatic calf compressors to prevent deep vein thrombosis (DVT). With the endotracheal tube placed to the side of the mouth, a preliminary flexible esophagogastroscope is performed to empty the diverticulum of all food and to examine the esophagus and the stomach. The scope is then brought back up into the oropharynx and moved into the pouch. The location of the diverticulum (on the left or the right side) is confirmed by turning off the room lights and noting which side is transilluminated by the gastroscope.

OPERATIVE TECHNIQUE

Step 1: Incision and Dissection of Pharyngeal Pouch

The patient lies with the head turned away from the side on which the incision is made (usually the left). The cricoid

cartilage is palpated and marked. A 6 cm skin incision is made, either obliquely along the sternocleidomastoid muscle [see Figure 1] or transversely in a skin crease at the level of the cricoid. The platysma is divided in the same line. Self-retaining retractors are inserted. The anterior border of the sternocleidomastoid muscle is incised throughout its length. The omohyoid muscle and the sternohyoid and sternothyroid muscles are retracted [see Figure 2]. The sternocleidomastoid muscle is retracted laterally to expose the carotid sheath and the internal jugular vein. The middle thyroid vein is ligated and divided, and the thyroid gland and the trachea are retracted medially by the assistant's finger to minimize the risk of injury to the underlying recurrent laryngeal nerve. There is no need to encircle the esophagus or to dissect in the tracheoesophageal groove. The deep cervical fascia is divided. The inferior thyroid artery is divided as laterally as possible. The carotid sheath is retracted laterally, and dissection is carried down to the prevertebral fascia [see Figure 2]. The endoscope placed in the diverticulum is palpated, and the pouch is dissected away from the cervical esophagus up as far as the pharyngoesophageal junction. The flexible endoscope is then removed from the pouch and advanced into the thoracic esophagus so that it can be used as a stent for the cricopharyngeal myotomy. Dissection of the pharyngeal pouch is then completed.

Figure 1 Cricopharyngeal myotomy and excision of Zenker diverticulum. A soft roll is placed behind the shoulders to extend the neck. The head is turned to the side opposite the incision. The cricoid cartilage is palpated and marked. The skin is incised obliquely along the sternocleidomastoid muscle, as shown, or transversely in a skin crease at the level of the cricoid.

Figure 2 Cricopharyngeal myotomy and excision of Zenker diverticulum. The sternocleidomastoid is incised along the anterior border so as to expose the omohyoid muscle and the sternohyoid and sternothyroid muscles, which are retracted. The thyroid gland and the trachea are retracted medially by the assistant's finger, and the inferior thyroid artery is ligated and divided laterally to avoid injury to the recurrent laryngeal nerve.

Step 2: Myotomy

The esophageal myotomy is started approximately 1 cm below the cricopharyngeus on the posterolateral esophageal wall [see Figure 3a]. The esophageal muscle is divided down to the mucosa, which is recognizable from its bluish coloration with the submucosal plexus overlying it. The esophageal muscle is dissected away from the mucosa with a right-angle dissector and divided with either a knife, scissors, or a low-intensity diathermy unit. The myotomy is then continued proximally through the cricopharyngeus and up into the muscular wall of the hypopharynx for 1 to 2 cm if no diverticulum is present. The hypopharynx is distinguished by a pronounced submucosal venous plexus. The muscle is then swept off the mucosa for 120°.

Step 3: Freeing or Excision of Diverticulum

If there is a diverticulum less than 2 cm in diameter, the cricopharyngeus is transected and the muscularis around the diverticulum is freed. The myotomy is extended onto the hypopharynx for 1 to 2 cm. The diverticulum is then suspended to the back wall of the pharynx to prevent food from easily entering it. It should not be sutured to the prevertebral fascia, because the passage of sutures through the diverticulum can contaminate the fascia or intervertebral disk, leading to an increased risk of infection.

If the diverticulum is more than 2 cm in diameter, it is excised with a linear stapler loaded with 2.5 mm staples, which is placed at the base of the sac and pressed firmly against the esophagoscope [see Figure 3b]. Particular care must be taken at this point so as not to injure the recurrent

laryngeal nerve. The stapler is fired, and the diverticulum is excised. The staple line is cleaned with an antiseptic solution, and the incision is filled with saline. The esophagus is insufflated with air to determine whether mucosal leakage has occurred, and the esophagoscope is removed; any mucosal leaks found are closed with fine absorbable sutures. In the absence of a stapler, the best way of excising the sac is to make a series of short incisions through the neck of the sac with scissors, suturing the edges after each cut with absorbable monofilament sutures (the so-called cut-and-sew technique). The esophagoscope ensures that the esophageal lumen is not narrowed. If an esophagoscope is not used, then a Maloney dilator (50 to 54 French) is used to ensure that excessive esophagus is not removed.

Step 4: Drainage and Closure

Once hemostasis has been achieved, a short vacuum drain is placed through the skin into the retroesophageal space. The platysma is repaired with absorbable sutures, and the skin is closed with a subcuticular absorbable suture. Nasogastric intubation is unnecessary. Prokinetic agents and PPIs are administered to prevent gastroesophageal reflux. A water-soluble contrast study can be done the day after the operation. If the results are normal, the patient is started on a liquid diet, the drain is removed, and the patient is discharged on liquids for 1 week.

COMPLICATIONS

The main complications associated with cricopharyngeal myotomy are recurrent laryngeal nerve trauma (occurring in 1% of cases), fistulas (1%), hematoma formation, infection (2%), aspiration, and recurrence (4%). Hematomas and infections must be drained promptly. Fistulas usually close once the prevertebral space is drained and the associated infection is controlled. Aspiration is the most serious complication after cricopharyngeal myotomy. Gastroesophageal reflux may contribute to oropharyngeal dysphagia. Division of the upper esophageal sphincter in a patient with an incompetent esophagogastric junction may lead to massive tracheobronchial aspiration. Therefore, documented severe gastroesophageal reflux, gastroesophageal regurgitation, and severe distal esophagitis may be relative contraindications to cricopharyngeal myotomy until the lower esophageal sphincter defect has been remedied with an antireflux operation.

OUTCOME EVALUATION

Of patients with a Zenker diverticulum, at least 90% experience excellent results from surgical treatment. Of patients without a Zenker diverticulum, one third experience excellent results, another third show moderate improvement, and the remaining third show no improvement.¹ Patients with poor pharyngeal contractility in conjunction with normal upper esophageal sphincter function show little improvement with cricopharyngeal myotomy. Patients with oropharyngeal dysphagia secondary to neurologic involvement who have intact voluntary deglutination, adequate pulsion of the tongue, and normal phonation may show improvement with cricopharyngeal myotomy. Appropriate selection of patients for cricopharyngeal myotomy leads to better surgical outcomes.

Figure 3 Cricopharyngeal myotomy and excision of Zenker diverticulum. (a) The diverticulum is dissected away from the esophagus, and an esophageal myotomy is started approximately 3 cm below the cricopharyngeus. The myotomy is continued proximally through the cricopharyngeus, and the muscle around the diverticulum is freed. (b) A linear stapler is placed at the base of the sac and pressed firmly against the esophagoscope. The stapler is fired, and the diverticulum is excised.

Transthoracic Hiatal Hernia Repair

Unlike most operations on the esophagus, which are extirpative procedures, hiatal hernia repair with fundoplication is a reconstructive procedure, the aim of which is to restore a high-pressure zone at the esophagogastric junction that prevents reflux but also permits comfortable swallowing. Currently, this repair is usually accomplished via minimally invasive approaches. The degree of tension on the hiatal repair sutures, the length of the esophagus, the quality of the crural tissue itself, and the caliber of the esophageal hiatus after repair all must be assessed. In certain patients, laparoscopic reconstruction of a competent gastroesophageal high-pressure zone may be very difficult and may demand a degree of skill not yet achievable by laparoscopy. The most common indications for transthoracic hiatus hernia repair are a failed previous repair and a hostile abdomen.

The long-term success of antireflux surgery, whether done via the transthoracic approach or by means of laparoscopy, depends on three factors: (1) a tension-free repair that maintains a 4 cm long segment of esophagus in the intra-abdominal position, (2) durable approximation of the diaphragmatic crura, and (3) correct matching of the fundoplication technique according to the peristaltic function of the esophagus. The transthoracic approach should be considered whenever the standard abdominal approaches to hiatal hernia repair carry an increased risk of failure or complication—for example, in patients who have a foreshortened esophagus associated with a massive hernia and an incarcerated intrathoracic stomach, patients with severe peptic strictures of

the esophagus, patients in whom the hiatal hernia coexists with an esophageal motility disorder or morbid obesity, and patients who have undergone multiple previous abdominal operations. The transthoracic repair is particularly useful when a previous open abdominal procedure has failed. In this situation, the reasons for such failure, whether technical or tissue related, should be assessed so that a compensatory strategy can be devised.

PREOPERATIVE EVALUATION

Symptomatic Evaluation

All patients being considered for fundoplication to treat GERD must undergo a comprehensive evaluation to determine whether there is indeed an anatomic substrate for their symptoms and what the most appropriate form of repair is. Specifically, a history of heartburn and effortless regurgitation should be sought. Dysphagia and odynophagia are not typically associated with hiatal hernia unless there is a significant paraesophageal component. Persistent dysphagia may reflect the presence of a stricture or a neoplasm. Reflux-induced esophageal spasm may present with occasional episodes of cervical dysphagia, but the transient nature of the symptoms easily differentiates this condition from dysphagia caused by a fixed obstruction. Chest pain that radiates toward the back after meals and is relieved by nonbilious vomiting may indicate the presence of an incarcerated intrathoracic stomach that is hindering the emptying of the paraesophageal component. Atypical chest pain from cholelithiasis, peptic ulcer, or coronary artery disease may confound the diagnosis.

Imaging

Radiographic investigation should begin with a ciné barium swallow, which will yield valuable information regarding the length of the esophagus, its peristaltic function, and the integrity of the mucosal surface. The gastric views can be used for qualitative assessment of distal emptying. Any paraesophageal component will be clearly demonstrated, along with any associated organoaxial volvulus. A simple barium swallow often yields the most useful information for managing the complex problem of recurrent hiatal hernia and a slipped Nissen fundoplication.

Next, esophagogastroscope should be performed to examine the mucosa for the presence of esophagitis, Barrett mucosa, stricture, or malignancy. The locations of any lesions observed, along with the position of the squamocolumnar junction, should be carefully documented in terms of their distance from the incisors. All strictures must undergo cup or brush biopsy to rule out an occult malignancy. The presence of severe esophagitis raises the possibility of acquired shortening of the esophagus secondary to transmural inflammation and contraction scarring. Every effort should be made to measure the length of the esophagus accurately.

Dilation

If a stricture is found during esophagoscopy, a decision must be made about whether to attempt esophageal dilation. This procedure carries the risk of perforation and should be performed only after careful consideration. If the stricture is diagnosed at the time of the initial endoscopic examination, it is advisable to perform only the brush biopsy at this point, deferring dilation to a subsequent visit. Delaying dilation gives the surgeon time to reassess the anatomy depicted on the barium swallow, to decide whether wire-guided dilation is necessitated by angulation of the esophagus, to obtain informed consent, to assemble the requisite equipment, and to plan sedation for what is often an uncomfortable procedure. If a malignancy is suspected at the time of the initial endoscopic examination, dilation should be avoided. In this situation, repair is impossible; thus, if iatrogenic perforation of a malignant stricture occurs, the surgeon will have to attempt emergency resection in an inadequately prepared patient in whom proper staging is unlikely to have been completed.

The standard flexible adult esophagoscope is approximately 32 French in caliber. In advancing the scope into the stricture, only very gentle pressure should be necessary. As a rule, a mild stricture that is not associated with steep angulation of the esophagus will readily accept passage of the endoscope and will be amenable to subsequent blind dilation with Hurst-Maloney bougies.

After successful passage, the scope is removed, and sequential insertion of progressively larger dilators (starting at 32 French) into the stricture is attempted. The weight of the dilator alone should be sufficient to effect its passage, with little or no forward force applied. Although the patient will be able to swallow comfortably only after satisfactory passage of a dilator at least 48 French in caliber, it is essential never to try to force passage. To this end, the surgeon must take careful note of the subtle signs of increasing resistance transmitted through the dilator. Sequential dilation should be stopped whenever significant resistance is encountered

or blood streaks appear on the dilator. Sudden pain during dilation is an ominous sign and calls for immediate investigation with a swallow study using a water-soluble contrast agent (e.g., Gastrografin, Schering AG, Berlin, Germany). Subcutaneous emphysema in the neck or mediastinal air on a plain chest radiograph may also indicate an injury to the esophagus. Perforation must be definitively ruled out before the patient can be discharged.

Highly stenotic strictures that do not allow the passage of a standard adult endoscope may be associated with a distorted and a steeply angulated esophagus. In such cases, the use of a pediatric endoscope may permit directed placement of a guide wire through the stricture; fluoroscopy is a useful adjunct for this purpose. A series of progressively larger Savary-Gillard dilators may then be passed over the guide wire to enlarge the lumen and allow subsequent endoscopic biopsy. As a rule, less tactile feedback is available during wire-guided dilation than during passage of standard Maloney-Hurst bougies. Increased pressure is required to pass the Savary-Gillard dilators because of the resistance caused by the wire passing through the dilator itself. It is essential that the wire be well lubricated and not be allowed to dislodge proximally between the sequential insertions of progressively larger dilators. The caveats that apply to blind dilation also apply to wire-guided dilation.

Patients whose esophagus can be dilated to 48 French and who are candidates for antireflux surgery may undergo subsequent intraoperative dilation to 54 to 60 French. Patients who cannot be dilated to 48 French and fail to achieve comfortable swallowing should be classified as having a nondilatable stricture and should be considered for transhiatal esophagectomy [see Resection of Esophagus and Proximal Stomach, *below*].

Functional Evaluation

Esophageal manometry permits quantitative assessment of peristalsis, a capability that is critically important for determining which type of fundoplication is most suitable for reconstructing a nonoccluding high-pressure zone at the esophagogastric junction. Stationary pH tests measure the capacity of the esophagus to clear acid, its sensitivity to instilled acid, the relation of reflux episodes to body position, and the correlation between changes in esophageal pH and the subjective symptoms of heartburn. Ambulatory 24-hour pH testing allows further quantification of reflux episodes with respect to duration, frequency, and association with patient symptoms.

OPERATIVE PLANNING

The transthoracic hiatus hernia repair may be completed with either a partial fundoplication (as in the 240° Belsey Mark IV procedure) or a complete fundoplication (as in the 360° Nissen procedure). Acquired shortening of the esophagus may necessitate lengthening of the esophagus by means of a Collis gastropasty, in which the portion of the gastric cardia along the lesser curvature and directly contiguous to the distal esophagus is fashioned into a tube [see Operative Technique, Step 6a, *below*].

A thoracic epidural catheter is placed for regional analgesia. General anesthesia is administered, and flexible esophagocopy is performed by the operating team. Insufflation should

be done with as little air as is practical, particularly in the case of large paraesophageal hernias. The extent of the pathologic condition is documented, and the absence of malignancy is verified. The stomach is decompressed with suction, and the endoscope is removed. A nasogastric tube is placed while the patient is supine.

Tracheal intubation is performed with a double-lumen endotracheal tube. A Foley catheter is placed. Subcutaneous heparin is administered for DVT prophylaxis, and pneumatic calf compression devices are applied. Antibiotic prophylaxis is provided.

The patient is positioned for a left thoracotomy. The table is flexed to distract the ribs. The right leg is bent at the hip and knee while the left leg is kept straight. Pillows are placed between the legs, and all pressure points are padded. The arms are positioned so that the humeri are at right angles to the chest and the elbows are bent 90°.

OPERATIVE TECHNIQUE

Step 1: Incision and Entry into Chest

A standard left posterolateral thoracotomy is performed. The latissimus dorsi is divided. The serratus fascia is incised, but the muscle itself can generally be preserved. For most patients, the sixth interspace is the most appropriate incision site for exposing the hiatus. The seventh interspace can also be used, particularly if the patient is tall or has a hyper-extended chest as a result of chronic pulmonary disease. The paraspinal muscles are elevated away from the posterior aspect of the adjacent ribs, and a 1 cm segment of the rib below the selected interspace is resected to facilitate exposure. The chest is then entered, and the lung and the pleural space are thoroughly inspected. The leaves of the retractor are spread slowly over the course of the next several minutes so as not to cause iatrogenic rib fractures.

Step 2: Mobilization of Esophagus and Excision of Hernia Sac

The inferior pulmonary ligament is divided with the electrocautery to the level of the inferior pulmonary vein [see Figure 4]. The mediastinal pleura overlying the esophagus is longitudinally incised to expose the esophagus from the level of the carina to the diaphragm. Particular care is taken to avoid injury to the vagi. Vessels supplying the esophagus and arising from the adjacent aorta are cauterized and divided. A few larger vessels may have to be ligated with 2-0 silk. The esophagus is encircled just below the inferior pulmonary vein with a wide Penrose drain [see Figure 4]. The two vagi are mobilized and carried with the esophagus. (The right vagus is located along the right anterior border of the descending aorta and can easily be missed.)

The esophagus is then elevated, and mobilization is circumferentially completed in the direction of the diaphragm, starting from the level of the carina. In cases of giant paraesophageal hernia or reoperation for a failed repair, the stomach will have a large intrathoracic component. Dissection continues inferiorly to separate the sac from the pericardium anteriorly and the aorta posteriorly. The right pleura is closely approximated to the esophagus for 2 to 5 cm above the diaphragm; in the presence of a substantial hiatal hernia and its sac, it may be difficult to identify. The right pleura should be gently dissected away from the sac without entry into the

Figure 4 Transthoracic hiatal hernia repair. The lung is retracted, and the inferior pulmonary ligament is divided to the level of the inferior pulmonary vein. The mediastinal pleura overlying the esophagus is incised to expose the esophagus from the level of the carina to the diaphragm. The esophagus and both vagi are encircled just below the inferior pulmonary vein with a Penrose drain. Vessels supplying the esophagus and arising from the adjacent aorta are ligated and divided.

right chest. This can generally be done with a small sponge on a stick. If a tear occurs, it should be closed with absorbable suture material to prevent accumulation of blood and fluid on the right side during the operation.

Dissection is continued inferiorly to expose the right and left crura. The left crus is generally more robust and is certain to be easily seen with this exposure. Its medial fibers may be attenuated and may blend into the hernia sac superiorly. The sac should be incised 1 cm above the muscle fibers because the muscle alone will not hold sutures well for the subsequent repair. Skeletonization of the crural muscle must be avoided; it is the fibroconnective tissue that provides the most tensile strength. The hernia sac is dissected away from the left crus in an anterior-to-posterior direction. The right crus is generally less robust than the left. In the case of a previous failed repair, the right crus may be very difficult to see, being obscured from the operator's view by the intrathoracic stomach. Dissection of the right crus is best accomplished in a posterior-to-anterior direction.

Once the sac is circumferentially freed from the crura, dissection proceeds cephalad along the esophagus. To minimize the risk of vagal injury, the sac should be incised parallel to the esophagus.

Step 3: Division of Phrenoesophageal Membrane and Gastrohepatic Ligament

The esophagus is retracted anteriorly to expose the posteriorly located phrenoesophageal membrane, which is

then divided to yield entry into the lesser sac. The remainder of the phrenoesophageal membrane is elevated with a right-angle clamp as it courses anteriorly, yielding a view of the spleen below. The esophagus and the stomach are thus completely mobilized from the left crus. The esophageal branch of the left phrenic artery, visible near the left vagus, is divided near the crus.

The uppermost portion of the gastrohepatic ligament is found along the undersurface of the right crus. It is divided with the electrocautery. The Belsey artery, a communicating branch between the left gastric artery and the inferior phrenic artery, lies in this area and may have to be ligated directly. It is vital to divide the gastrohepatic ligament down to the level of the left gastric artery. The caudate lobe of the liver must be clearly visible beneath the right crus. This opening is essential for subsequent passage of the fundoplication wrap behind the esophagus.

Step 4: Mobilization of the Stomach

The highest short gastric arteries are ligated between ties to permit mobilization of the fundus. Excessive traction must be avoided to prevent splenic injury. Three or four vessels are usually divided. The esophagogastric junction is elevated well into the chest, and any organoaxial rotation of the stomach is released as the short gastric vessels are divided. It is crucial that ligation be limited to the vessels along the greater curvature. Inadvertent ligation of the vessels along the lesser curvature can easily occur, especially if there was a previous operation. Loss of blood supply from the branches of the left gastric artery along the lesser curvature will lead to ischemia of the Collis gastroplasty tube and will predispose to either leakage at the staple line or subsequent stricture formation.

In the case of a redo repair, the previous fundoplication often will have slipped down onto the cardia or even onto the body of the stomach. Generally, the inner aspect of the previous fundoplication can be freed from the esophagus without any difficulty; rarely will any major dissection have been done in this area during the original operation. The vagi will be found within the wrap and should be specifically visualized. Because of scarring, it may be difficult to see the point at which the previous fundoplication attaches to itself. Not uncommonly, a serosal tear develops on the fundus as the wrap is undone. Any areas of concern can be reinforced with a simple stitch of 4-0 silk. Mobilization is complete when the fundus is restored to its original anatomic position and the greater curvature can be followed down to the left gastroepiploic artery.

Step 5: Closure of Crura

Because the right crus is often quite attenuated, it is crucial to incorporate an adequate amount of tissue into the repair. An Allis or Babcock clamp is placed at the apex of the hiatus and into the central tendon so that both crura can be placed under tension. The esophagus is retracted anteriorly, and a No. 1 silk suture is passed through the most posterior aspect of the left crus, with care taken to avoid the adjacent spleen [see Figure 5]. A notched spoon retractor is placed through the hiatus and into the abdomen behind the left crus. The spleen is thus protected while the suture is brought through the left crus.

Figure 5 Transthoracic hiatal hernia repair. The esophagogastric junction is mobilized by dividing the phrenoesophageal ligament and some short gastric vessels. No. 1 silk sutures are passed through the exterior aspect of the right crus (with care taken to avoid the adjacent inferior vena cava) and through the left crus.

Next, the suture is brought out through the right crus, with care taken to prevent injury to the aorta or entry through the right pleura. Three to five crural repair stitches are then placed at 1 cm intervals, from posterior to anterior. The sutures should be staggered slightly so that the needle entry points are not all in a straight line; this measure helps prevent longitudinal shredding of the muscle fibers when the sutures are placed under tension. The sutures are held together with hemostats but left untied at this point in the operation.

Placement of traction on the last suture should close the defect while still allowing easy passage of one finger along the esophagus. The final decision on whether to tie this last suture or to cut it out is made later, after construction of the fundoplication. It is better to err on the side of an overly narrow opening; removing a suture is easier than having to place an extra one at a time when exposure is less than optimal.

Step 6: Assessment of Esophageal Length and Removal of Anterior Fat Pad

After placement of the crural stitches, an assessment of the esophageal length is made. Ideally, the stomach can easily be reduced into the abdomen without placing tension on the thoracic esophagus. When esophageal foreshortening is found, a Collis gastroplasty is performed [see Step 6a, below].

If an esophageal stricture is present, the assistant performs dilation by passing a tapered bougie orally while the surgeon supports the esophagus. The anteriorly located esophageal fat pad is removed in anticipation of the gastroplasty, with care taken not to injure the vagi located on either side [see Figure 6].

Figure 6 Transthoracic hiatal hernia repair. The anterior fat pad is removed from the esophagus with sharp dissection, with care taken to avoid injury to the vagi.

Step 6a: Collis Gastroplasty

In a Collis gastroplasty for a short esophagus, a stapler is used to form a 4 to 5 cm neoesophagus out of the proximal stomach, thereby effectively lengthening the esophagus and transposing the esophagogastric junction more distally. A large-caliber Maloney bougie (54 French for women, 56 French for men) is placed in the esophagus to prevent narrowing of the lumen as the stapler is fired. The bougie is advanced well into the stomach so that its widest portion rests at the esophagogastric junction. The bougie is held against the lesser curvature, and the fundus is retracted away at a right angle to the esophagus with a Babcock clamp. A 60 mm gastrointestinal anastomosis (GIA) stapler loaded with 3.5 mm staples is applied immediately alongside the bougie on the greater curvature side [see Figure 7a] and fired, simultaneously cutting and stapling the cardia. The staple line is oversewn with nonabsorbable 4-0 monofilament suture material on both sides [see Figure 7b]. Two metal clips are placed to mark the distal extent of the gastroplasty tube, denoting the new esophagogastric junction.

Step 7: Fundoplication and Reduction of Wrap into Abdomen

The fundus is passed posteriorly behind the esophagus and brought up against the anterior stomach, with care taken to avoid torsion of the fundal wrap. The fundus is then wrapped either over the lower 2 cm of the esophagus, if no gastroplasty was done, or over a 2 cm length of the gastroplasty tube while the bougie is in place. The seromuscular layer of the fundus is approximated to that of the esophagus or the gastroplasty tube and that of the adjacent anterior stomach with two interrupted 2-0 silk sutures [see Figure 8]. When tied, the wrap should still be loose enough to accommodate a finger alongside the esophagus. The fundoplication sutures are

again oversewn with a continuous seromuscular nonabsorbable monofilament suture. Two clips are placed at the superior aspect of the wrap. These, along with the previously placed clips, help confirm both the length and the location of the wrap on chest x-ray.

Once the fundoplication is complete, the dilator is removed and the wrap is reduced into the abdomen. Two mattress sutures of 2-0 polypropylene are placed to secure the top of the fundoplication to the underside of the diaphragm. The crural sutures are then sequentially tied, from the most posterior one to the most anterior. When the final suture is tied, one finger should still be able to pass through the hiatus alongside the esophagus.

Step 8: Drainage and Closure

A nasogastric tube is passed into the stomach and secured. Hemostasis is verified, and a single thoracostomy tube is placed. The wound is closed in layers. A chest x-ray is performed to verify the position of the tubes and the location of the clips marking the wrap. The patient is then extubated in the operating room (OR) and transported to the recovery area.

POSTOPERATIVE CARE

Patients typically remain in the hospital for about 5 days. The nasogastric tube is left on low suction and removed on postoperative day 3. Patients then begin liquid oral intake, advancing to a full-fluid diet as tolerated. Early ambulation is encouraged to prevent respiratory complications. Judicious use of analgesics and antiemetics minimizes nausea and vomiting. The thoracostomy tube is removed as drainage subsides. The epidural and Foley catheters are generally removed later the same day. A barium swallow is performed on postoperative day 5 to verify the position of the wrap, to ensure that there is no significant esophageal obstruction, and to provide a qualitative impression of gastric emptying. Gastroparesis secondary to vagal nerve dysfunction may be apparent.

Once patients can tolerate a soft solid diet, they are discharged home with instructions about the gradual resumption of a normal diet at home. Large meals and carbonated beverages should be avoided in the early postoperative period.

COMPLICATIONS

The root causes of the complications arising after transthoracic hiatal hernia repair are often technical; thus, the best prevention, in most cases, is meticulous surgical technique. Mobilization of the stomach with ligation of short gastric vessels may result in injury to the spleen. Injury to the vagi predisposes to gastric dysfunction, early satiety, and so-called gas-bloat syndrome. Poor crural approximation increases the chances that the repair will fail. Dehiscence allows upward migration of the wrap into the chest or the development of a paraesophageal hernia. The gastroplasty may leak at the staple line. Overzealous dissection along the lesser curvature can devascularize the cardia and cause ischemic stenosis of the gastroplasty tube. Torsion of the fundus results in perforation and sepsis. Excessive distraction of the ribs can lead to pain and splinting with subsequent atelectasis or pneumonia. Inadequate mobilization of the fundus may place

Figure 7 Transthoracic hiatal hernia repair. (a) If esophageal foreshortening is present, a Collis gastroplasty is performed. A 54 French Maloney bougie is inserted through the esophagogastric junction. A 4 to 5 cm neoesophagus is formed with a 60 mm gastrointestinal anastomosis stapler loaded with 3.5 mm staples. (b) Both the fundal staple line and the lesser curvature staple line are oversewn with nonabsorbable monofilament suture.

excessive tension on the wrap and promote later disruption and recurrent reflux. A slipped Nissen can result when the wrap is inadequately fixed to the esophagus or the gastroplasty tube and the stomach telescopes through the intact fundoplication to assume an hourglass configuration. This event leads to varying degrees of heartburn, regurgitation, and dysphagia because the proximal pouch tends to empty

slowly and remain distended after meals. A wrap that is too tight or too long results in persistent dysphagia.

Recurrent heartburn and regurgitation call for evaluation with contrast studies and esophagoscopy. The barium swallow is the most useful test for assessing whether the repair has failed. If there is an anatomic condition that is responsible for recurrent symptoms (e.g., slipping of the fundoplication or disruption of the crural repair), reoperation is usually necessary; continued medical treatment of symptoms related to a structural failure invariably proves to be of little use. A barium swallow may also identify gastroparesis secondary to vagal nerve injury. Nuclear transit studies for gastric emptying will help confirm this diagnosis. Dysphagia that is not related to recurrent reflux, ulceration, or stricture usually responds to dilation; reoperation is not required if the barium swallow shows contrast flowing through the esophagus and an intact wrap beneath the diaphragm. Given that patients with long-standing reflux are at higher risk for Barrett dysplasia and esophageal adenocarcinoma, it is important to perform endoscopy to rule out malignancy.

OUTCOME EVALUATION

Transthoracic hiatal hernia repair yields good to excellent results in more than 85% of patients undergoing a primary repair. Approximately 75% of patients who have previously undergone hiatal hernia repair experience symptomatic improvement.²

Resection of Esophagus and Proximal Stomach

In the remainder of the chapter, we describe the standard open techniques for resection of the esophagus and the esophagogastric junction. The technique of esophagectomy is largely surgeon dependent, with often strong preferences expressed for a particular operative approach. There is a

Figure 8 Transthoracic hiatal hernia repair. The fundus is passed behind the esophagus and sewn to the neoesophagus and the anterior stomach over a 2 cm length with interrupted 2-0 silk sutures.

paucity of definitive evidence as to which technique is superior. Transhiatal esophagectomy is commonly performed to treat end-stage benign esophageal disease and carcinomas of the cardia and the lower esophagus. Esophageal resection through a combined laparotomy–right thoracotomy approach (Ivor Lewis esophagectomy) is ideal for cancers of the middle esophagus but is also used by many for lower third cancers. A three-hole esophagectomy (also known as a McKeown esophagectomy) is sometimes preferred for its excellent exposure of all lymph node stations. The gastric conduit may be anastomosed to the cervical esophagus either high in the right chest (as in an Ivor Lewis esophagectomy) or in the neck (as in a transhiatal esophagectomy or three-hole esophagectomy). The left thoracoabdominal approach is less commonly used but may be indicated for resection of the distal esophagus and the proximal stomach in the case of a bulky tumor that is locally aggressive. Although the traditional anastomosis of the gastric conduit is in the left chest, it may also be placed in the neck.

PREOPERATIVE EVALUATION

Thorough preoperative preparation is essential for a good postoperative outcome. Smoking cessation and a graded regimen of home exercise will help minimize postoperative complications and encourage early mobilization. Schematic diagrams have proved useful for educating patients and shaping their expectations about quality of life and ability to swallow after esophagectomy. Illustrations, by emphasizing the anatomic relations, greatly facilitate discussion of potential complications (e.g., hoarseness from recurrent laryngeal nerve injury, pneumothorax, anastomotic leakage, mediastinal bleeding, and splenic injury).

Potential postoperative problems (e.g., reflux, regurgitation, early satiety, dumping, and dysphagia) must be discussed before operation. Such discussion is particularly relevant for patients undergoing esophagectomy for early-stage malignant tumors or for high-grade dysplasia in Barrett mucosa. These patients generally have no esophageal obstruction and may be completely asymptomatic; accordingly, their expectations about postoperative function may be quite different from those of patients with profound dysphagia secondary to near-complete esophageal occlusion. Support groups in which patients with upcoming operations can contact patients who have already undergone treatment have proved to be highly beneficial to all parties. Realistic expectations improve the chances of a satisfactory outcome.

Evaluation of Operative Risk

Preoperative assessment should include a thorough review of the patient's cardiopulmonary reserve and an estimate of the level of operative risk. Spirometry, arterial blood gas analysis, and exercise stress testing should be considered. Even when a transhiatal esophagectomy is planned, patients should be assessed with an eye to whether they can tolerate a laparotomy and a thoracotomy, in case the latter is made necessary by findings that become apparent only at the time of operation. Thoracic epidural analgesia should be administered for pain control. If a transthoracic approach is taken, a double-lumen endotracheal tube should be placed for separate lung ventilation before beginning the chest portion of the resection.

Imaging

Esophagoscopy with biopsy and contrast-enhanced CT of the chest and the upper abdomen are required before esophagectomy. If performed, the esophagogram identifies the location of the tumor and may indicate whether it extends into the proximal stomach. Esophagoscopy allows direct assessment of the mucosa, precise localization of the tumor, and collection of tissue for histologic study. Retroflexion views of the stomach, after distention with air, are particularly important if proximal gastric invasion is suspected, in which case distal esophagectomy and total gastrectomy with reconstruction of alimentary continuity by means of intestinal interposition may be required. In cases of midesophageal cancer, bronchoscopy is mandatory to rule out airway involvement. The carina and the proximal left mainstem bronchus are the sites most at risk for local invasion.

Contrast-enhanced CT scans of the chest and abdomen are standard. Thoracic and abdominal CT scans yield information on the extent of any celiac or mediastinal adenopathy, the degree of esophageal thickening, and the possibility of invasion of the adjacent aorta or tracheobronchial tree. The lung parenchyma is assessed for metastatic nodules, as are the liver and the adrenal glands. When the distal extent of tumor cannot be defined as a result of near-complete obstruction on endoscopy, a prone abdominal CT scan can help differentiate a tumor at the gastric cardia from a collapsed but normal stomach. If the obstruction is not complete, the stomach can be distended with air (through either the ingestion of effervescent granules or the passage of a small-bore nasogastric tube) to improve visualization. A prone CT scan also yields improved imaging of the gastrohepatic and celiac lymph nodes by allowing the stomach to fall away from these adjacent structures. Metastatic cancer in the celiac lymph nodes portends a poor prognosis.

PET is useful for the detection of occult distant metastases that preclude curative resection. Suspicious areas should undergo needle biopsy or laparoscopic or thoracoscopic assessment. Similarly, pleural effusions must be tapped for cytologic evaluation. Invasion of mediastinal structures and the presence of distant metastases are contraindications to esophagectomy.

At present, EUS, although quite sensitive for detection of paraesophageal adenopathy, is incapable of accurately differentiating reactive lymph nodes from nodes invaded by malignancy. EUS-FNA of suspicious lymph nodes should be done if possible. This is often not possible because of intervening tumor in the wall of the esophagus. CT and PET have limitations; thus, locoregional involvement may not be recognized before resection is attempted. In patients who are marginal candidates for surgical treatment and in whom metastatic disease is suspected, laparoscopy has been advocated for histologic evaluation of small superficial liver nodules, peritoneal abnormalities, and celiac nodes. Although this approach adds to the cost of investigation, it can save the patient from having to undergo a major operation for what would later prove to be an incurable condition.

Neoadjuvant Therapy

Patients with esophageal cancer who are candidates for resection may benefit from neoadjuvant chemotherapy and

concurrent radiation therapy. In particular, patients with good performance status and locally advanced disease should be considered for such therapy. To date, no randomized trials have conclusively demonstrated a survival benefit with this approach, but several series have documented a 20 to 30% rate of complete response with no viable tumor found at the time of resection. After chemoradiation, patients are restaged with a CT. PET after treatment may yield spurious results in that inflammatory conditions can mimic the increased tracer uptake seen in malignant tissue. Microscopic disease cannot be assessed, and scarring from radiation may further confound the situation by preventing tracer uptake in areas that actually harbor malignancy.

If there are no contraindications to surgical treatment, resection is scheduled 4 to 6 weeks after the completion of neoadjuvant therapy. This interval allows time for patients to return to their baseline activity level and for any induced hematologic abnormalities to be corrected. Previous chemoradiation therapy does not make transhiatal esophagectomy significantly more difficult or complicated. Many tumors are downstaged and less bulky at the time of resection. In centers with experience in this approach, the rates of bleeding and anastomotic leakage remain low.

OPERATIVE PLANNING

Transhiatal Esophagectomy

In transhiatal esophagectomy, the stomach is mobilized through an upper midline laparotomy, the esophagus is mobilized from adjacent mediastinal structures via dissection through the hiatus without the use of a thoracotomy, and the stomach is transposed through the posterior mediastinum and anastomosed to the cervical esophagus at the level of the clavicles. The main advantages of this approach are (1) a proximal surgical margin that is well away from the tumor site, (2) an extrathoracic esophagogastric anastomosis that is easily accessible in the event of complications, and (3) reduced overall operative trauma. Single-center studies throughout the world have shown transhiatal esophagectomy to be safe and well tolerated, even in patients who may have significantly reduced cardiopulmonary reserve. Long-term survival is equivalent to that reported after transthoracic esophagectomy.

Although transhiatal esophagectomy has been used for resection of tumors at any location in the esophagus, it is best suited for resection of tumors in the lower esophagus and at the esophagogastric junction. It should also be considered for certain advanced nonmalignant conditions of the esophagus. Nondilatable strictures of the esophagus may occur as an end-stage complication of gastroesophageal reflux. Intractable reflux after failed hiatal hernia repair may not be amenable to further attempts at reconstruction of the esophagogastric junction and thus may call for esophagectomy. Because of the high cervical anastomosis, transhiatal esophagectomy is less likely to predispose to postoperative reflux and recurrent stricture formation than transthoracic esophagectomy would be. Achalasia may result in a sigmoid megaesophagus and dysphagia that cannot be managed without removal of the esophagus. Transhiatal esophagectomy permits complete removal of the thoracic esophagus and, in the majority of patients, restoration of comfortable swallowing without the need for a thoracotomy.

Generally, patients are admitted to the hospital on the day of the operation. Thoracic epidural analgesia is administered, both intraoperatively and postoperatively, and appropriate antibiotic prophylaxis is provided. Heparin, 5,000 U subcutaneously, is given before induction, and pneumatic calf compression devices are applied. A radial artery catheter is placed to permit continuous monitoring of blood pressure. Central venous access is rarely required. General anesthesia is administered via an uncut single-lumen endotracheal tube. Flexible esophagoscopy is performed (if it was not previously performed by the surgical team). A nasogastric tube is placed before final positioning and draping.

The patient is placed in the supine position with a small rolled sheet between the shoulders. The arms are secured to the sides, and the head is rotated to the right with the neck extended. The neck, the chest, and the abdomen are prepared as a single sterile field. The drapes are placed so as to expose the patient from the left ear to the pubis. The operative field is extended laterally to the anterior axillary lines to permit placement of thoracostomy tubes as needed. A self-retaining table-mounted retractor is used to facilitate upward and lateral traction along the costal margin.

Ivor Lewis Esophagectomy

At many institutions, Ivor Lewis esophagectomy is preferred because it provides excellent direct exposure for dissection of the intrathoracic esophagus in that it combines a right thoracotomy with a laparotomy. This procedure should be especially considered when there is concern regarding the extent of esophageal fixation within the mediastinum. One advantage of Ivor Lewis esophagectomy is that an extensive local lymphadenectomy can easily be performed through the right thoracotomy. Any attachments to mediastinal structures can be freed under direct vision. Whether any regional lymph node dissection is necessary is highly controversial; no significant survival advantage has yet been demonstrated. Long-term survival after Ivor Lewis resection is equivalent to that after transhiatal esophagectomy.³

The main disadvantages of the Ivor Lewis procedure are (1) the physiologic impact of the two major access incisions employed (a right thoracotomy and a midline laparotomy) and (2) the location of the anastomosis (in the chest). Incision-related pain may hinder deep breathing and the clearing of bronchial secretions, resulting in atelectasis and pneumonia. The use of thoracic epidural catheters for pain management has greatly improved pain-related respiratory complications. Complications of the intrathoracic anastomosis may be hard to manage. Although the anastomotic leakage rate associated with Ivor Lewis esophagectomy has typically been 5% or lower—and thus substantially lower than the rate cited for the cervical anastomosis after transhiatal esophagectomy—intrathoracic leaks are much more dangerous and difficult to handle than intracervical leaks. In many cases, drainage of the leak will be incomplete and empyema will result. Reoperation may prove necessary to manage mediastinitis.

Three-Hole Esophagectomy

Three-hole esophagectomy is performed when the surgeon desires direct exposure to all phases of dissection, extensive lymph node clearance, and an anastomosis in the neck. The

right chest is opened first, and the intrathoracic esophagus and the regional lymph nodes are dissected and mobilized free. The patient is then turned supine for the abdominal and neck phase, very similar to a transhiatal esophagectomy.

Left Thoracoabdominal Esophagogastrectomy

The left thoracoabdominal approach is indicated for large gastroesophageal junction tumors and resection of the distal esophagus and the proximal stomach when removal of the stomach necessitates the use of an intestinal substitute to restore swallowing. This approach can also be used for very obese patients to obtain optimal exposure. If the proximal stomach must be resected for adequate resection margins to be obtained, then the distal stomach may be anastomosed to the esophagus in the left chest. This operation can be associated with significant esophagitis from bile reflux. Consequently, many surgeons prefer to resect the entire stomach and the distal esophagus and then to restore swallowing with a Roux-en-Y jejunal interposition anastomosed to the residual thoracic esophagus. Alternatively, some surgeons use this approach for most cancers and routinely place the anastomosis in the left neck. Similar to other transthoracic approaches, the use of a thoracic epidural catheter for pain control ameliorates pain-related respiratory complications.

OPERATIVE TECHNIQUE

Transhiatal Esophagectomy

Transhiatal esophagectomy is best understood as consisting of three components: abdominal, mediastinal, and cervical. The abdominal portion involves mobilization of the stomach, pyloromyotomy (if performed), and placement of a temporary feeding jejunostomy.

Step 1: incision and entry into peritoneum A midline laparotomy is performed from the tip of the xiphoid to the umbilicus. The peritoneum is opened to the left of the midline so that the falciform and the preperitoneal fat may be retracted en bloc to the right. Body wall retractors are placed at 45° angles from the midline to elevate and distract both costal margins. The retractors are placed so as to lift up the costal margin gently and open the wound. The abdomen is then inspected for metastases.

Step 2: division of gastrohepatic ligament and mobilization of distal esophagus The left lobe of the liver is mobilized by dividing the triangular ligament and then folded to the right and held in this position with a moist laparotomy pad and a deep-bladed self-retaining retractor. Next, the gastrohepatic ligament is divided. Occasionally, there is an aberrant left hepatic artery arising from the left gastric artery [see Figure 9]. The peritoneum over the right crus is incised, and the hiatus is palpated; the extent and mobility of any tumor may then be assessed. The peritoneum over the left crus is similarly divided, and the esophagus is encircled with a 2.5 cm Penrose drain. Traction is applied to draw the esophagogastric junction upward and to the right; this measure facilitates exposure of the short gastric arteries coursing to the fundus and the cardia.

Step 3: mobilization of stomach The greater curvature of the stomach is inspected, and the right gastroepiploic

artery is palpated. The lesser sac is generally entered near the midpoint of the greater curvature. The transition zone between the right gastroepiploic arcade and the short gastric arteries is usually devoid of blood vessels.

Dissection then proceeds along the greater curvature toward the pylorus. The omentum is mobilized from the right gastroepiploic artery. Vessels are ligated between 2-0 silk ties, and great care is exercised to avoid placing excessive traction on the arterial arcade. A 1 cm margin is always maintained between the line of dissection and the right gastroepiploic artery. Venous injuries, in particular, can occur with injudicious handling of tissue. The ultrasonic scalpel is particularly efficient and effective for mobilization of the stomach; again, this instrument must be applied well away from the gastroepiploic arcade. Dissection is continued rightward to the level of the pylorus. It should be noted that the location of the gastroepiploic artery in this area may vary; often it is at some unexpected distance from the stomach wall. Posterior adhesions between the stomach and the pancreas are lysed so that the lesser sac can be completely opened.

The assistant's left hand is then placed into the lesser sac to retract the stomach gently to the right and place the short gastric vessels on tension. The Penrose drain previously placed around the esophagus facilitates exposure by retracting the cardia to the right. Dissection along the greater curvature proceeds cephalad. The vessels are divided well away from the wall of the stomach to prevent injury to the fundus. Clamps should never be placed on the stomach. A high short gastric artery is typically encountered just adjacent to the left crus. Precise technique is required to prevent injury to the spleen. The Penrose drain [see Step 2, above] is exposed as the peritoneum is opened over the left crus. Mobilization of the proximal stomach and liberation of the distal esophagus are thereby completed.

Once the stomach has been completely mobilized along the greater curvature, it is elevated and rotated to the right [see Figure 10]; the left gastric artery and associated nodal tissues can then be visualized via the lesser sac. The superior edge of the pancreas is visible, and the remaining posterior attachments of the stomach are divided along the hiatus and the left crus. These may be quite extensive if there has been a history of pancreatitis or preoperative radiation therapy.

If the operation is being done for malignant disease, a final determination of resectability can be made at this point. Tumor fixation to the aorta or the retroperitoneum can be assessed. Celiac and para-aortic lymph nodes can be palpated and, if necessary, sent for biopsy. The left gastric artery and vein are then ligated proximally, either through the lesser sac or directly through the divided gastrohepatic ligament. All nodal tissue is dissected free in anticipation of subsequent removal en bloc with the specimen.

Step 4: mobilization of duodenum and pyloromyotomy The duodenum is mobilized with a Kocher maneuver. Careful attention to the superior extent of this dissection is critical. Adhesions to either the porta hepatis or the gallbladder must be divided to ensure that the pylorus is sufficiently freed for later migration to the diaphragmatic hiatus.

Gastric drainage can be provided by a pyloromyotomy and is performed by most surgeons. The pyloromyotomy is begun 1 to 2 cm on the gastric side of the pylorus. The serosa and

Figure 9 Transhiatal esophagectomy. The duodenum is mobilized, and the gastrohepatic and gastrocolic omenta are divided.

the muscle are divided with a small scalpel to expose the submucosa; generally, these layers of the stomach are robust, making the proper plane easy to find.

Dissection is extended toward the duodenum with the aid of a fine-tipped right-angle or tonsil clamp. The duodenal submucosa, recognizable by its fatty deposits and yellow coloration, is exposed for approximately 0.5 cm. The duodenal submucosa is usually much more superficial than expected, and accidental entry into the duodenum often occurs just past the left edge of the circular muscle of the pylorus. Should entry into the lumen occur, a simple repair using interrupted fine monofilament (4-0 or 5-0 polypropylene) sutures to close the mucosa is performed. Small metal clips are applied to the knots of the traction sutures before removal of the ends; these clips serve to indicate the level of the pyloromyotomy on subsequent radiographic studies. A tag of omentum can be easily sutured over the myotomy site for an added layer of security. My own preference is not to perform a pyloromyotomy primarily to reduce the possibility of postoperative bile reflux, which is very problematic to treat. In addition, I remain unconvinced that pyloromyotomy helps gastric drainage that much. With the availability of balloon dilation, it is now simple to enhance emptying postoperatively if needed. Many studies have confirmed that not performing a pyloromyotomy is safe.

Step 5: feeding jejunostomy Placement of a standard Weitzel jejunal feeding tube approximately 30 cm from the

ligament of Treitz completes the abdominal portion of the transhiatal esophagectomy.

Step 6: exposure and encirclement of cervical esophagus

The cervical esophagus is exposed through a 6 to 8 cm incision along the anterior edge of the left sternocleidomastoid muscle [see Figure 1] that is centered over the level of the cricoid cartilage. The platysma is divided to expose the omohyoid, which is divided at its tendon. The strap muscles are divided low in the neck at their origin on the back of the manubrium. The esophagus and its indwelling nasogastric tube can be palpated.

The carotid sheath is retracted laterally, and blunt dissection is employed to reach the prevertebral fascia. The inferior thyroid artery is ligated laterally; the recurrent laryngeal nerve is visible just deep and medial to this vessel. No retractor other than the surgeon's finger should be applied medially: traction injury to the recurrent laryngeal nerve will result in both vocal cord palsy and uncoordinated swallowing with aspiration. In particular, metal retractors must not be used in this area. The tracheoesophageal groove is incised close to the esophageal wall while gentle finger traction is applied cephalad to elevate the thyroid cartilage toward the right. This measure usually suffices to define the location of the nerve.

The esophagus is then encircled by passing a right-angle clamp posteriorly from left to right while the surgeon's finger remains in the tracheoesophageal groove. The tip of the

Figure 10 Transhiatal esophagectomy. After the stomach has been completely mobilized along the greater curvature, it is elevated and rotated to the right. The left gastric vessels are suture-ligated and divided. A 1 cm margin of the diaphragmatic crura is taken in continuity with the esophagogastric junction, providing ample clearance of the tumor and improved exposure of the lower mediastinum. *A* denotes the aorta, *E* denotes the esophageal hiatus.

clamp is brought into the pulp of the fingertip. The medially located recurrent laryngeal nerve and the membranous trachea are thereby protected from injury. The clamp is brought around, and a narrow Penrose drain is passed around the esophagus [see Figure 11]. Blunt finger dissection is employed to develop the anterior and posterior planes around the esophagus at the level of the thoracic inlet.

Step 7: mediastinal dissection Some authors describe this portion of the procedure as a blunt dissection, but, in fact, the vast majority of the mediastinal mobilization is done under direct vision. Narrow, long-handled, handheld, curved Harrington retractors are placed into the hiatus and lifted up to expose the distal esophagus. Caudal traction is placed on the esophagus, allowing excellent visualization of the hiatus and the distal esophagus. Long right-angle clamps are used to expose these attachments. Vascularity in this area is often minimal, and hemostasis can easily be achieved with either the electrocautery, ultrasonic scalpel, metal clips, or ties. The left crus can be divided to facilitate exposure. Paraesophageal lymph nodes are removed either en bloc or as separate specimens. Dissection is continued cephalad with the electrocautery and a long-handled right-angle clamp. The two vagi

are divided, and the periesophageal adhesions are lysed. Mobilization of the distal esophagus under direct vision is thus completed up to the level of the carina.

Three specific maneuvers are now carried out. First, the plane posterior to the esophagus is developed [see Figure 12]. The surgeon's right hand is advanced palm upward into the hiatus, with the fingers closely applied to the esophagus. The volar aspects of the fingers run along the prevertebral fascia, elevating the esophagus off the spine. A moist sponge stick is placed through the cervical incision, also posterior to the esophagus. The sponge is advanced toward the right hand, which is positioned within the mediastinum. As the sponge is advanced into the right palm, the posterior plane is completed.

Second, the anterior plane is developed [see Figure 13]. This is often much more difficult than developing the posterior plane because the left mainstem bronchus may be quite close to the esophagus. Again, the surgeon's right hand is placed through the hiatus, but it is now palm down and anterior to the esophagus. The fingertips enter the space between the esophagus and the left mainstem bronchus. The hand is gently advanced, and the airway is displaced anteriorly. A blunt curved suction handle is employed from above as a

Figure 11 Transhiatal esophagectomy. Once the cervical esophagus is exposed through an incision along the left sternocleidomastoid muscle, strap muscles are divided and retracted, and the cervical esophagus is dissected away from the left and right recurrent laryngeal nerves.

substitute finger. It is advanced along the anterior aspect of the esophagus through the cervical incision. The right hand guides the tip of the suction handle beneath the bronchus. Lateral displacement of the handle allows further mobilization of the bronchus away from the esophagus. Completion of the anterior and posterior planes usually results in a highly mobile esophagus.

Third, the lateral attachments of the upper and middle esophagus are divided. Upward traction is applied with the Penrose drain previously placed around the cervical esophagus, allowing further dissection at the level of the thoracic inlet. Lateral attachments are pushed caudally into the mediastinum, and traction applied to the esophagus from below allows these attachments to be visualized inferiorly through the hiatus and then isolated with long right-angle clamps and divided with the electrocautery. Caution must be exercised so as not to injure the azygos vein. Dissection on the right side must therefore be kept close to the esophagus. Once the last lateral attachment is divided, the esophagus is completely free and can be advanced into the cervical wound.

Close monitoring of arterial blood pressure is maintained throughout. Transient hypotension may occur as a result of mediastinal compression and temporary impairment of cardiac venous return as the surgeon's hand or retractors are passed through the hiatus. Vasopressors are never required for management: simple repositioning of the retractors or removal of the dissecting hand usually results in prompt restoration of normal blood pressure. Placement of the patient in a slight Trendelenburg position is often helpful.

Figure 12 Transhiatal esophagectomy. The plane posterior to the esophagus is developed by placing the surgeon's right hand into the hiatus along the prevertebral fascia. A moist sponge stick is placed through the cervical incision posterior to the esophagus, and the posterior plane is completed.

Step 8: proximal transection of esophagus and delivery into abdomen The nasogastric tube is retracted to the level of the cricopharynx, and the esophagus is divided with a cutting stapler 5 to 6 cm distal to the muscle. The esophagus is then removed via the abdomen [see Figure 14]. Retractors are placed in the hiatus, and the mediastinum is inspected for hemostasis. Both pleurae are inspected. The lungs are inflated so that it can be determined which pleural space requires thoracostomy drainage. The mediastinum is packed with dry laparotomy pads from below. A narrow pack is placed into the thoracic inlet from above. Chest tubes are then placed as required along the inframammary crease in the anterior axillary line. The drainage from these tubes should be closely monitored throughout the rest of the operation to ensure that any bleeding from the mediastinal dissection does not go unnoticed.

Step 9: excision of specimen and formation of gastric tube The gastric fundus is grasped, and gentle tension is applied along the length of the stomach. The esophagus is held at right angles to the body of the stomach, and the fat in the gastrohepatic ligament is elevated off the lesser curvature; all lymph nodes are thus mobilized. A point approximately midway along the lesser curvature is selected. The blood vessels traversing this area from the right gastric artery are

Figure 13 Transhiatal esophagectomy. The anterior plane is developed by placing the surgeon's right hand through the hiatus anterior to the esophagus. The fingertips enter the space between the esophagus and the left mainstem bronchus, to be met by a blunt suction handle passed downward through the cervical incision. The lateral attachments of the esophagus are divided from above downward as far as the aortic arch.

ligated to expose the lesser curvature. The distal resection margin is then marked; it should be 4 to 6 cm from the esophagogastric junction, extending from the selected point on the lesser curvature to a point medial to the fundus. A 60 mm GIA stapler loaded with 3.5 or 4.8 (depending on the thickness of the stomach) mm staples is then used to transect the proximal stomach, proceeding from the lesser curvature toward the fundus [see Figure 15]. Resection of the cardia along with the adjacent portion of the lesser curvature effectively converts a J-shaped stomach into a straight tube and harvests many left gastric territory lymph nodes.

For maximizing the length of the gastric tube, several technical points are critical. Tension must be maintained on the stomach as the stapler is serially applied. The stapler should be simply placed on the stomach and fired: no attempt should be made to telescope tissue into the jaws because to do so would effectively reconstitute the curve of the stomach and diminish its upward reach. Typically, five or six staple loads are required.

The specimen is removed, and frozen-section examination is done on the distal margin. The completed staple line is then oversewn with a continuous Lembert suture of 4-0 polypropylene. Once again, tension is maintained along the stomach to prevent any foreshortening of the lesser curvature. The use of two separate sutures, each reinforcing half of the staple line, is helpful in this regard. Alternatively, interrupted 4-0 sutures can be used.

Step 10: advancement of stomach into chest or neck

The mediastinal packs are removed, and hemostasis is verified in the chest. The stomach is inspected as well. The ends of any short gastric vessels that were divided with the

Figure 14 Transhiatal esophagectomy. The esophagus is divided in the neck and delivered into the abdomen. Retractors are placed in the hiatus, and any vessels entering into the esophagus are clipped and divided. The vagi are also clipped and divided.

Figure 15 Transhiatal esophagectomy. A gastric tube is formed by stapling along the lesser curvature of the stomach from the junction of the right and left gastric vessels to the top of the fundus. This staple line is oversewn with either an interrupted or a continuous fine suture, with care taken not to foreshorten the gastric tube. The gastric tube is made at least 5 cm wide to avoid undo ischemia.

ultrasonic scalpel are now tied so that subsequent manipulation does not precipitate bleeding. The stomach is oriented so that the greater curvature is to the patient's left. There must be no torsion. The anterior surface of the fundal tip should be marked with ink so that proper orientation of the stomach can be confirmed after its passage into the neck. The stomach can usually be advanced through the posterior mediastinum without any traction sutures or clamps. The surgeon's hand is placed palm down on the anterior surface of the stomach, with the fingertips about 5 cm proximal to the tip of the fundus. The hand is then gently advanced through the chest, pushing the stomach ahead of itself. The tip of the fundus is gently grasped with a Babcock clamp as it appears in the neck. To prevent trauma at this most distant aspect of the gastric tube, the clamp should not be ratcheted closed.

No attempt should be made to pull the stomach up into the neck: the position of the fundus is simply maintained as the surgeon's hand is removed from the mediastinum. Further length in the neck can usually be gained by gently readvancing the hand along the anterior aspect of the stomach. This measure uniformly distributes tension along the tube and ensures proper torsion-free orientation in the chest. The stomach is pushed up into the neck rather than drawn up by the clamp.

A useful alternative approach for positioning the gastric tube involves passing a large-bore Foley catheter through the mediastinum from the neck incision. The balloon is inflated, and a 50 cm section of a narrow plastic laparoscopic camera bag is tied onto the catheter just above the balloon. The gastric tube is positioned within the bag, and suction is applied through the catheter, creating an atraumatic seal between the stomach and the surrounding plastic bag. As the bag is drawn upward through the neck with gentle traction on the Foley catheter, the stomach advances through the mediastinum. The stomach is not secured to the prevertebral fascia in any way.

The feeding jejunal tube is brought out the left midabdomen through a separate stab incision. The hiatus is inspected

for hemostasis, as is the splenic hilum. It may be necessary to reconstitute the hiatus with one or two simple sutures of 1-0 silk placed through the crura. These sutures must be placed with care to ensure that injury to the gastroepiploic arcade does not occur at this late point in the procedure. The hiatus is narrowed, but not so much that three fingers cannot be easily passed alongside the gastric conduit. This reconstitution will help prevent herniation of other abdominal contents alongside the gastric conduit. The liver is returned to its anatomic position, thus also preventing any subsequent herniation of bowel into the chest. The pylorus is generally found at the level of the diaphragm. The laparotomy is then closed in the usual fashion. The viability of the fundus in the neck incision is checked periodically as the abdominal portion of the procedure is completed.

Step 11: cervical esophagogastric anastomosis The construction of the esophagogastric anastomosis is the most important part of the entire operation: any anastomotic complication will greatly compromise the patient's ability to swallow comfortably. Accordingly, meticulous technique is essential.

A seromuscular traction suture of 4-0 polyglactin is placed through the anterior stomach at the level of the clavicle and drawn upward, thus elevating the fundus into the neck wound and greatly facilitating the anastomosis.

The site of the anterior gastrotomy is then carefully selected: it should be midway between the oversewn lesser curvature staple line and the greater curvature of the fundus (marked by the ligated ends of the short gastric vessels). The staple line on the cervical esophagus is removed, and the anterior aspect of the esophagus is grasped with a fine-toothed forceps at the level of the planned gastrotomy. A straight DeBakey forceps is then applied across the full width of the esophagus to act as a guide for division. The esophagus is cut with a new scalpel blade at a 45° angle so that the anterior wall is slightly longer than the posterior wall; the anterior wall then forms the hood of the anastomosis. The fine-toothed forceps is used to maintain orientation of the esophagus throughout. Two

full-thickness stay sutures of 4-0 polyglactin are placed, one at the midpoint of the anterior cut edge of the esophagus and one at the corresponding location posteriorly. The posterior stitch is placed from inside the lumen, and the needle is left on the suture for later use.

A small gastrotomy is then performed with a needle-tipped electrocautery using cutting current. The incision is obliquely oriented, with the cephalad extent proceeding slightly medially. The needle from the stay suture previously placed on the posterior wall of the esophagus is then passed the full thickness of the cephalad aspect of the gastrotomy [see Figure 16a]. Traction on this untied suture brings the esophagus toward the stomach. A 45 mm endoscopic stapler loaded with 3.5 mm staples is used to form the back wall of the anastomosis. The thicker portion of the device (the cartridge) is advanced cephalad into the esophagus, with the narrower portion (the anvil) in the gastric lumen [see Figure 16b]. The tip of the stapler should be aimed toward the patient's right ear. Tension is applied to the stay suture holding the esophagus and stomach together so as to bring tissue into the jaws of the device. The portion of the fundus extending beyond the stapler is then rotated medially to ensure that the new staple line is well away from the one previously placed along the lesser curvature. This is a crucial point: crossing of the two staple lines may create an ischemic area that can give rise to a large leak in the postoperative period.

The stapler is then closed, holding the esophagus and stomach together, but not yet fired. The position of the nasogastric tube should be maintained just at the level of the cricopharyngeus during the construction of the anastomosis. This positioning keeps the tube out of the operative field and protects it from being entrapped by the jaws of the stapler; it also facilitates subsequent passage of the tube into the gastric conduit once the posterior wall of the anastomosis is complete. Two suspension sutures are placed on either side of the closed stapler, one toward the tip and the other near the heel of the jaws. These four sutures alleviate any potential tension on the staple line by approximating the muscular layer of the esophagus to the seromuscular layer of the stomach. The suspension sutures are tied, and the stapler is fired, thereby completing the posterior portion of the anastomosis [see Figure 16c].

The anterior portion of the anastomosis is closed in two layers. The inner layer consists of a continuous 4-0 polydioxanone suture placed as full-thickness inverting stitches, and the second layer consists of interrupted seromuscular Lembert sutures [see Figure 17]. The lateral and medial corners of the anastomosis, where the staple line meets the handsewn portion, merit extra attention. These corners are quite fragile, and excessive traction may result in dehiscence progressing cephalad along the staple line in a zipperlike fashion. The inner layer should therefore be started at each corner, incorporating the last 5 mm of the staple line. Once several stitches have been placed from the two corners, the nasogastric tube can be passed through the anastomosis. The nasogastric tube is properly positioned when the most distal black marker is at the nares. The inner layer is then completed as the two sutures are tied at the midpoint.

Step 12: drainage, closure, and completion x-ray The incision is irrigated. The strap muscles are not reapproximated but are merely attached loosely to the underside of the

Figure 16 Transhiatal esophagectomy. (a) After the proximal end of the stomach tube is delivered into the neck, the esophagus is cut at a 45° angle so that the anterior wall is longer than the posterior wall. A gastrotomy is placed between the oversewn lesser curvature staple line and the greater curvature of the fundus. A full-thickness suture is placed through all layers of the esophagus and all layers of the gastrotomy. (b) An endoscopic gastrointestinal anastomosis stapler is used to form the back wall of the anastomosis. The thicker portion of the device (the cartridge) is advanced cephalad into the esophagus, with the narrower portion (the anvil) in the gastric lumen. The tip of the stapler should be aimed toward the patient's right ear. The staple line must be well away from the lesser curvature staple line. Two suspension sutures are placed on either side of the closed stapler, one toward the tip and the other near the heel of the jaws. (c) The stapler is fired to complete the posterior portion of the anastomosis.

Figure 17 Transhiatal esophagectomy. The anterior portion of the anastomosis is completed with (a) an inner layer consisting of a continuous 4-0 polydioxanone suture and (b) an outer layer consisting of interrupted sutures.

sternocleidomastoid muscle with two interrupted 4-0 polyglactin sutures. The platysma is reconstituted with interrupted 4-0 polyglactin sutures. The nasogastric tube is secured.

A chest x-ray is obtained in the OR to verify the position of the drains and the absence of any abnormal collections in the chest. Patients are extubated in the OR and transported to the anesthetic recovery area. Extubation should be carried out only when the health care team is confident that subsequent reintubation is unlikely to be necessary. Emergency reintubation after a cervical anastomosis is hazardous in that vigorous neck extension may threaten the suture line. Once patients are awake and alert, which is usually 3 to 4 hours after the operation, they are taken to the general ward. As a rule, admission to an intensive care unit is not required unless there are substantial comorbidities or intraoperative concerns. To prevent excessive traction on the anastomosis, the neck should be maintained in a flexed position with two pillows placed behind the head.

In certain patients, a stapled anastomosis may be impractical. In patients with a bull-neck habitus, for example, a partial sternal split may be required for adequate exposure of the cervical esophagus, and a handsewn true end-to-end anastomosis (EEA) may be necessary. In addition, patients who have previously undergone antireflux surgery may have a relatively short gastric tube that will necessitate an end-to-end reconstruction.

Patients should, if possible, begin walking the morning after the operation. An incentive spirometer should be constantly within arm's length of the patient, and hourly use of this device should be encouraged. The nasogastric tube is removed on postoperative day 3, and the patient is allowed

ice chips in the mouth. The thoracic epidural catheter is removed the afternoon after the chest tube is removed. The diet is gradually advanced so that a soft diet is begun on postoperative day 5 or 6. A barium swallow is performed on postoperative day 6 in preparation for hospital discharge on day 7 or 8.

Ivor Lewis Esophagectomy

Steps 1 through 5 Esophagoscopy is performed to confirm the location of the tumor. Steps 1 through 5 of an Ivor Lewis esophagectomy are virtually identical to the first five steps (i.e., the abdominal portion) of a transhiatal esophagectomy. Once complete mobilization of the stomach is verified, the pylorus is manually advanced to the level of the diaphragm to ensure that it is not being tethered by the duodenum or the greater omentum. Although it is possible to form the gastric tube in the chest, it is easier to do in the abdomen. Similar to step 9 in a transhiatal esophagectomy, a 5 to 6 cm wide gastric tube is created. The proximal divided stomach is sewn to a large Penrose drain. The other end of the drain is sutured to the tip of the gastric tube so that it can be pulled into the chest when needed. A jejunostomy is performed, and the laparotomy is closed.

Step 6: exposure and mobilization of esophagus The patient is shifted to the left lateral decubitus position and redraped. Single-lung ventilation is instituted, and the chest is entered through a right fifth interspace thoracotomy. The inferior pulmonary ligament is divided, and the lung is retracted cephalad. The esophagus is mobilized from the level of the diaphragm to a point above the azygos vein [see Figure 18], which can be divided with a vascular stapler. I prefer not to divide the vein as the azygos helps keep the stomach conduit in the midline for comfortable swallowing. The pleura overlying the esophagus is divided to the level of the thoracic inlet, superior to the azygos vein. The esophagus is encircled with a Penrose drain in the retrotracheal region. The pleura is then divided to the level of the diaphragm, with care taken to stay close to the right bronchus and the pericardium and avoid injury to the thoracic duct. The soft tissue between the esophagus and the aorta posteriorly and between the esophagus and the trachea or the pericardium anteriorly is dissected free and maintained en bloc with the esophagus. Periesophageal and subcarinal nodes are thereby mobilized [see Figure 18b].

Step 7: excision and removal of specimen The hiatus is incised, and the abdomen is entered. The stomach is drawn up into the chest, with care taken not to place excessive traction on the gastroepiploic pedicle. The esophagus is divided proximally at least 5 cm away from any grossly evident tumor, typically just below the thoracic inlet. The esophageal specimen is removed from the operative field, and proximal and distal margins are sent for frozen-section examination. [see Figure 19]. The stomach is positioned in the posterior mediastinum with care to avoid any twisting.

Step 8: intrathoracic esophagogastric anastomosis The site of the esophagogastric anastomosis should be about 2 to 4 cm above the azygos vein. Several interrupted sutures are used to secure the transposed stomach to the adjacent pleura. The staple line on the esophagus is removed, and a

Figure 18 Ivor Lewis esophagectomy. (a) The lung is retracted, and the azygos vein is stapled and divided. The esophagus and the vagi are mobilized from the level of the diaphragm to the thoracic inlet. (b) Dissection en bloc via right thoracotomy of the thoracic duct, the azygos vein, the ipsilateral pleura, and all periesophageal tissue in the mediastinum. The specimen includes the lower and middle mediastinal, subcarinal, and right-side paratracheal lymph nodes.

gastrotomy is performed in preparation for a side-to-side functional EEA [see Figure 20]. With the aid of full-thickness traction sutures, the esophagus is positioned along the surface of the stomach and well away from the oversewn staple line defining the gastric resection margin. The posterior aspect of the anastomosis is completed with an endoscopic GIA stapler as described earlier [see Transhiatal Esophagectomy, Step 11, above, and Figure 16 and Figure 17]. A nasogastric tube is passed, and the anterior wall is completed in two layers. The first layer consists of a full-thickness continuous 3-0 polydioxanone suture; the second consists of interrupted absorbable sutures approximating the seromuscular layer of the stomach to the muscular layer of the esophagus.

Two alternative methods of anastomosis are sometimes used: (1) a totally handsewn end-to-side anastomosis and (2) a totally stapled EEA. I prefer a handsewn anastomosis, although it is no longer in vogue. An outer layer of interrupted 4-0 silk is used followed by a mucosal layer of interrupted inverting 4-0 silk [see Figure 20]. The stapled circular technique involves opening the previously placed gastric staple line and advancing the handle of an EEA stapler

through the stomach. The proximal esophagus is dilated sufficiently to accommodate at least a 25 mm head. The anvil is placed into the distal esophagus and secured with a purse-string suture. The tip of the stapler is brought out through the apical wall of the stomach and attached to the anvil. The stapler is then fired to create the EEA, and the gastrotomy is closed. The advantages of this technique are its relative simplicity and the theoretical security of a completely stapled anastomosis; the main potential disadvantage is the risk of postoperative dysphagia resulting from an overly narrow anastomotic ring.

After completion of the anastomosis, the stomach is inspected for any potential redundancy or torsion in the chest. To prevent torsion, the stomach is anchored to the pericardium and pleura with nonabsorbable sutures. The diaphragmatic hiatus is then inspected: it should allow easy passage of two fingers into the abdomen alongside the transposed stomach. Interrupted sutures may be used to approximate the edge of the crura to the adjacent stomach wall, thereby preventing any later herniation of abdominal contents into the pleural space.

Figure 19 Ivor Lewis esophagectomy. (a) After full mobilization of the esophagus, the gastric conduit (sutured to the divided proximal stomach) is pulled up into the chest. (b) An open anastomosis is begun at or above the level of the azygos vein.

Step 9: drainage and closure A chest tube is placed. The tip of the chest drain is positioned alongside the stomach at the level of the anastomosis. Fine gut sutures secured to the adjacent parietal pleura will help maintain the position of the tube. The thoracotomy is then closed in the standard fashion.

Patients should begin walking on postoperative day 1. The nasogastric tube is generally removed on postoperative day 3. Oral intake is not begun at this point; feeding is accomplished via the temporary jejunostomy. A barium contrast study is performed approximately 5 to 7 days after the operation. If there is no anastomotic leakage, oral intake is initiated and advanced as tolerated. The chest tube and epidural catheter are removed, usually on day 4. Patients are generally discharged from the hospital by postoperative days 8 to 10.

Three-Hole Esophagectomy

Step 1: thoracotomy phase Esophagoscopy is performed to confirm the location of the tumor. A double-lumen endotracheal tube is placed. The first step is a right thoracotomy and mobilization of the esophagus and the regional lymph nodes, similar to step 6 of an Ivor Lewis esophagectomy. The chest is closed after esophageal mobilization is performed.

Step 2: abdominal and cervical phase The patient is turned back to the supine position. The double-lumen

endotracheal tube is replaced by a standard single-lumen tube. Thereafter, the operation proceeds exactly like a transhiatal esophagectomy with steps 1 through 12. The mediastinal phase is, of course, much easier because all of the dissection was done in the thoracotomy phase of the operation.

Patients should begin walking on postoperative day 1. The nasogastric tube is generally removed on postoperative day 3. Oral intake is not begun at this point; feeding is accomplished via the temporary jejunostomy. A barium contrast study is performed approximately 5 to 7 days after the operation. If there is no anastomotic leakage, oral intake is initiated and advanced as tolerated. The chest tube and epidural catheter are removed, usually on day 4. Patients are generally discharged from the hospital by postoperative days 8 to 10.

Left Thoracoabdominal Esophagogastrrectomy

Step 1: incision and entry into peritoneum The patient is placed in the right lateral position, with the hips rotated backward about 30°. An exploratory laparotomy is performed through an oblique incision extending from the tip of the sixth costal cartilage to a point about halfway between the sternum and the umbilicus. The peritoneal cavity is carefully examined to rule out peritoneal and hepatic metastases. The region of the cardia is palpated, and the mobility of the tumor is assessed. If there is minor involvement of the crura or the

Figure 20 Ivor Lewis esophagectomy. The two-layer anastomosis is performed with fine 4-0 sutures in an interrupted fashion. It is important to locate the gastrostomy away from the turned-in lesser curve suture line to avoid ischemia. (a) Posterior layer. (b) Posterior inner mucosal layer. (c) Anterior mucosal layer. (d) After the anterior seromuscular layer is done, local pleura is used to cover the anastomosis to buttress it and to keep the conduit in the middle of the mediastinum. The anastomosis can also be completed as in a transhiatal esophagectomy or with an end-to-end anastomosis [see Figure 16 and Figure 17].

tail of the pancreas, resection may still be possible; however, if the tumor is firmly fixed or there are peritoneal or hepatic metastases, resection should be abandoned. A feeding jejunostomy, an esophageal stent, or both may be inserted to improve swallowing and allow nutrition.

Step 2: assessment of gastric involvement and incision of diaphragm The extent to which the tumor involves the stomach determines whether a total gastrectomy or a proximal gastrectomy is indicated along with the distal esophagectomy. If no metastases are found, the incision is extended and the chest is opened with a left posterolateral incision through the sixth interspace. If the thoracic component of the tumor appears to be resectable, the costal margin is divided. It is advisable to remove a 1 to 2 cm segment of the costal margin to facilitate repair of the diaphragm at the end of the operation and reduce postoperative costal margin pain. The diaphragm is incised radially. Alternatively, a circumferential incision may be made about 2 cm from the costal margin to reduce the risk of postoperative diaphragmatic paralysis.

Step 3: division of pulmonary ligament and mobilization of esophagus and stomach The pulmonary ligament is divided, and the mediastinal pleura is incised over the esophagus as far as the aortic arch. The esophagus is mobilized above the tumor and is retracted by a Penrose drain. The esophageal vessels are carefully dissected, ligated, and

divided. The tumor is mobilized; the plane of the dissection is kept close to the aorta on the left, and, if necessary, the right parietal pleura is taken in continuity with the lesion. About 1 cm of the crura is taken in continuity with the tumor to provide good local clearance. The stomach is then mobilized in much the same way as in a transhiatal esophagectomy [see Figure 9].

Step 4: assessment of pancreatic involvement and hepatic viability The lesser sac is opened through the greater omentum so that it can be determined whether the primary tumor involves the distal pancreas. If so, it is reasonable to resect the distal pancreas, the spleen, or both in continuity with the stomach; if not, the short gastric vessels are ligated and divided, with the spleen preserved. The lesser omentum is detached from the right side of the esophagus and the hilum of the liver and then divided down to the area of the pylorus, with the right gastric artery and vein preserved. There is often a hepatic branch from the left gastric artery running through the gastrohepatic omentum. If this hepatic branch is of significant size, a soft vascular clamp should be placed on the artery for 20 minutes so that the viability of the liver can be assessed. If the liver is viable, the artery is suture-ligated and divided.

Step 5: division of greater omentum and short gastric vessels The greater omentum is divided, with care taken to

preserve the right gastroepiploic artery and vein. These two vessels are suture-ligated and divided well away from the stomach. Ligation and division of the short gastric vessels allow complete mobilization of the greater curvature of the stomach. Dissection is extended downward as far as the pylorus. The stomach is turned upward, and the left gastric vessels are exposed through the lesser sac [see Figure 10]. The lymph nodes along the celiac axis and the left gastric artery are swept up into the specimen, and the gastric vessels are either suture-ligated or stapled and divided.

Step 6: choice of partial or total gastrectomy At this time, the surgeon determines whether the whole stomach must be resected to remove the gastric part of the cancer or whether a partial (i.e., proximal) gastrectomy will suffice.

If the surgeon decides that resection of the proximal stomach will remove all of the tumor while leaving at least 5 cm of tumor-free stomach, a proximal esophagogastrrectomy is performed [see Figure 21]. A gastric tube is fashioned with a linear stapler [see Transhiatal Esophagectomy, Step 9, above, and Figure 15]. The staple line is oversewn with inverting 3-0 or 4-0 sutures. Because the vagus nerves are divided and gastric stasis may result, a pyloromyotomy may be performed, much as in a transhiatal esophagectomy.

The proximal gastric resection margin is covered with a sponge and turned upward over the costal margin. The stomach tube is then brought up through the hiatus and into the thorax behind the proximal esophageal resection margin [see Figure 21]. The margin should be at least 10 cm from the proximal end of the esophagogastric cancer. If the esophageal resection margin is not adequate, the stomach tube is mobilized and brought to the left neck and then anastomosed

to the cervical esophagus through a left neck incision; alternatively, the left colon is interposed between the gastric stump and the cervical esophagus. If the resection margin is adequate, the tip of the stomach tube is anastomosed to the esophagus by any of the previously described techniques [see Figure 22].

The anastomosis is then performed with the stapling technique previously described for transhiatal esophagectomy [see Figure 16 and Figure 17]. A nasogastric tube is passed down into the gastric remnant. The tube is sewn to the pericardium and the endothoracic fascia to prevent torsion or herniation into the pleural space.

Total gastrectomy with Roux-en-Y esophagojejunostomy If the surgeon decides that a total gastrectomy is necessary, the right gastroepiploic and right gastric vessels are suture-ligated and divided distal to the pylorus. The duodenum is divided just distal to the pylorus with a linear stapler. The staple line is inverted with interrupted 3-0 nonabsorbable sutures and covered with omentum to prevent duodenal stump blowout.

The esophagus is then mobilized up to the level of the inferior pulmonary vein. Two retaining sutures are placed in the esophageal wall. A monofilament nylon purse-string suture is placed around the circumference of the proximal esophagus in preparation for stapling. The resected specimen is sent to the pathologist for examination of the margins.

A jejunal interposition is then fashioned by using the Roux-en-Y technique. One or two jejunal arteriovenous arcades are divided to mobilize enough jejunum to allow anastomosis to the thoracic esophagus [see Figure 23]. A 25 or 28 mm EEA stapler is passed through the jejunum into the

Figure 21 Left thoracoabdominal esophagogastrrectomy. The diaphragm is incised radially sparing major branches of the phrenic nerve. The pulmonary ligament is divided, and the esophagus is mobilized above the tumor and retracted with a Penrose drain. The esophageal vessels are ligated and divided. The tumor and the esophagus are mobilized off the aorta down to the hiatus; 1 cm of the diaphragmatic crura is taken in continuity with the tumor to provide local clearance. The stomach is then mobilized in much the same way as in a transhiatal esophagectomy and brought through the diaphragmatic hiatus [see Figure 9].

Figure 22 Left thoracoabdominal esophagogastrectomy: proximal esophagogastrectomy with esophagogastrostomy. The esophagus is sewn to the tip of the stomach tube, halfway between the lesser curvature suture line and the greater curvature. (a) The Sweet anastomosis developed at the Massachusetts General Hospital. The outer posterior layer is performed with fine 4-0 silk sutures. A serosal “button” is inscribed with a scalpel down to the level of the submucosal vascular plexus. Fine 4-0 silk sutures are used to ligate these vessels so they do not obscure the anastomosis while it is being performed. (b) The gastric button is excised, and the inner posterior layer is anastomosed with interrupted 4-0 silks. This is continued anteriorly as well. (c) The outer anterior layer is performed also with interrupted 4-0 silks. (d) A tag of omentum from the high greater curve is sutured over the anastomosis to buttress it. Alternatively, an anastomosis can be fashioned with the stapling technique used in transhiatal esophagectomy or with an end-to-end anastomosis [see Figure 16 and Figure 17].

esophagus, fired, and removed. The jejunum is anchored to the pericardium and the proximal esophagus. The duodenal loop is anastomosed to the jejunum at least 45 to 50 cm distal to the esophagojejunal anastomosis to minimize bile reflux [see Figure 23]. The blind end of the jejunal loop is then stapled closed.

After careful irrigation of the chest, the first step in the closure is to repair the diaphragm around the hiatus. The gastric or jejunal interposition is sewn to the crura with interrupted nonabsorbable sutures. The remainder of the diaphragm is closed with interrupted nonabsorbable 0 mattress sutures. A chest tube is placed into the pleural space close to but not touching the anastomosis. The final sutures in the peripheral part of the diaphragm are placed but are not tied until the ribs are brought together with pericostal sutures. The left lung is reexpanded. The costal cartilages are not approximated but are left to float free. If the ends of the costal margin are abutting, another 2 cm of costal cartilage should be removed to reduce postoperative pain. Thoracic and abdominal skin layers are closed with a continuous

absorbable suture. The skin and the subcutaneous tissue are closed in the usual fashion.

POSTOPERATIVE CARE

As a rule, patients are not routinely admitted to the intensive care unit after esophagectomy; however, individual practices depend on the distribution of skilled nursing and physiotherapy personnel. Early ambulation is the mainstay of postoperative care. As a rule, patients are able to walk slowly, with assistance, on postoperative day 1. Patient-controlled epidural analgesia is particularly useful in facilitating good pulmonary toilet and minimizing the risk of atelectasis or pneumonia.

The nasogastric tube is removed on postoperative day 3 or 4; jejunostomy tube feedings are gradually started at the same time. Once bowel function normalizes, patients are allowed small sips of liquids. Chest tubes are removed as pleural drainage subsides. By postoperative day 6, most patients have progressed to a soft solid diet. Dietary education is provided, focusing primarily on eating smaller and more frequent meals,

Figure 23 Left thoracoabdominal esophagogastrectomy: total gastrectomy with Roux-en-Y esophagojejunostomy. A jejunal interposition is fashioned with the Roux-en-Y technique. One or two jejunal arteriovenous arcades are divided to mobilize enough jejunum for anastomosis to the thoracic esophagus. A 25 or 28 mm end-to-end anastomosis stapler is passed through the jejunum into the esophagus. The jejunum is anchored to the pericardium and the proximal esophagus. The duodenal loop is anastomosed to the jejunum at least 45 to 50 cm distal to the esophagojejunal anastomosis. The blind end of the jejunal loop is then stapled closed.

avoiding bulky foods (e.g., meat and bread) in the early postoperative period, and taking measures to minimize postprandial dumping. Patients are also taught how to care for their temporary feeding jejunostomy. Consumption of caffeine and carbonated beverages is usually limited during the first few weeks after discharge.

A barium swallow is performed on postoperative day 7 to verify the integrity of the anastomosis and gastric emptying. Patients are usually discharged on postoperative day 7 or 8. The feeding jejunostomy is left in place until the first postoperative evaluation, which usually takes place 2 to 3 weeks after the operation. The feeding tube is removed during that visit if oral intake and weight are stable.

COMPLICATIONS OF ESOPHAGECTOMY

Pulmonary Impairment

Atelectasis and pneumonia should be considered preventable complications of esophagectomy. Patients with

recognized preoperative impairment of pulmonary reserve should be considered for transhiatal esophagectomy. Existing pulmonary function can be optimized through incentive spirometry, use of bronchodilators, and physical rehabilitation. Chronic nocturnal aspiration from esophageal obstruction should be watched for in the postoperative patient; the head of the bed should be elevated 30° to 45° as a preventive measure. Effective pain control is essential to prevent postoperative atelectasis. Routine use of patient-controlled thoracic epidural analgesia should be considered. Deep breathing, early ambulation, and chest physiotherapy encourage the clearing of bronchial secretions. Certain patients will require nasotracheal aspiration or bronchoscopy for pulmonary toilet.

Tracheobronchial Injury

On rare occasions, lacerations of the membranous trachea or the left mainstem bronchus occur during esophagectomy. When such injuries occur during transthoracic resection, management is relatively simple, thanks to the already excellent operative exposure. Direct suture repair and tissue reinforcement with adjacent pleura or a pedicle of intercostal muscle provide safe closure in almost all cases. When tracheobronchial injuries occur during transhiatal esophagectomy, they are less obvious but no less urgent. This rare complication arises during mediastinal dissection. Typically, the anesthetic team notes a loss of ventilatory volume, and the surgeon may detect the smell of inhalational agents in the operative field. Bronchoscopy should be promptly performed to identify the site of the injury. The uncut endotracheal tube is then advanced over the bronchoscope and past the site of the laceration to restore proper ventilation. High tracheal injuries can usually be repaired by extending the cervical incision and adding a partial sternotomy. Injury to the carina or the left mainstem bronchus must be repaired via a right thoracotomy.

Bleeding

Hemorrhage should be rare during esophagectomy. In routine situations, blood loss should amount to less than 500 mL. The blood supply to the esophagus consists of small branches coming from the aorta, which are easily controlled and generally constrict even if left untied. Splenic injuries sometimes occur during mobilization of the stomach. The resultant hemorrhage can be immediate or delayed; blood loss may be significant, and splenectomy is usually required. Precise dissection around the left gastric artery is vital: the bleeding vessels may retract, and attempts at control may result in injury to the celiac artery or its hepatic branches. Similarly, peripancreatic vessels may be difficult to control if inadvertently injured during the Kocher maneuver.

Bleeding that arises during the mediastinal stage of the transhiatal esophagectomy generally subsides with packing if it derives from periesophageal arterial branches. Brisk loss of dark blood usually signifies injury to the azygos vein. The first step in addressing such injuries is to pack the mediastinum quickly so as to allow the anesthetic team to stabilize the patient and restore volume. Chest tubes are immediately placed to allow detection of any free hemorrhage into the pleural space. Precise localization of the bleeding site may then follow. Injury to the azygos vein may be addressed via

an upper sternal split; however, when the exposure is poor, the surgeon should not hesitate to proceed to a full sternotomy. Bleeding from the subcarinal area is usually bright red and may involve bronchial arteries or small periesophageal vessels arising from the aorta, both of which can usually be controlled through the hiatus with a long-handled pistol-grip clip applicator or electrocautery.

Laryngeal Nerve Injury

Injury to the recurrent laryngeal nerve is a major potential complication of transhiatal esophagectomy. Traction neuropraxia may be temporary and require no specific treatment. Permanent injury will lead to hoarseness and impaired protection of the airway during deglutition. Pneumonia from aspiration is a major problem. Meticulous protection of the nerve during the cervical stage should minimize the incidence of this complication. If laryngeal nerve injury becomes apparent in the postoperative period, early medialization of the affected cord should be performed by an otolaryngologist to enhance the ability of the patient to cough and to prevent aspiration.

Of particular concern is the risk of bilateral nerve injury after a transthoracic esophagectomy with a cervical esophago-gastric anastomosis (i.e., a so-called three-hole esophagectomy). Any dissection of the upper esophagus performed through the right chest should be done as close to the esophagus as possible to avoid placing traction on the right recurrent laryngeal nerve; the subsequent left cervical dissection may put the left recurrent laryngeal nerve at risk for damage. Bilateral paralysis of the vocal cords is very poorly tolerated and has a devastating impact on quality of life.

Chylothorax

Thoracic duct injuries typically present by postoperative day 3 or 4. Dyspnea and pleural effusion may be noted if thoracostomy tubes are not in place. Thoracentesis yields an opaque, milky fluid. In patients who already have a chest drain in place, there is typically a high volume of serous drainage in the first 2 postoperative days. As enteral nutrition is established and dietary fat is reintroduced, the fluid assumes a characteristic milky appearance. In most cases, the gross appearance is diagnostic, and there is rarely a need to confirm the diagnosis by measuring the triglyceride level. A thoracostomy drain is placed to monitor the volume of the chyle leak if one is not present. Chest x-rays should be obtained to verify complete drainage of the pleural space and full expansion of the lung.

Patients with chylothorax should be converted to fat-free enteral nutrition. Persistent drainage exceeding 500 mL per day is an indication for early operation and ligation of the thoracic duct; high-volume chyle leaks are unlikely to close spontaneously. Prolonged loss of chyle causes significant electrolyte, nutritional, and immunologic derangements that may prove fatal if allowed to progress. Accordingly, patients with persistent chyle leakage should undergo operation within 1 week of diagnosis. A feeding tube is placed in the duodenum before operation if a jejunostomy tube is not already in place. Jejunal feeding with 35% cream at a rate of 60 to 80 mL/hr is maintained for at least 4 hours before operation. Feeding is continued even during the procedure: the enteral

fat stimulates a brisk flow of chyle and greatly facilitates visualization of any thoracic duct injury.

Right-side chyle leaks are approached via either a thoracotomy or video-assisted thoracoscopy. The magnification and excellent illumination associated with thoracoscopy are partially counterbalanced by the constraints imposed by port placement and limited tissue retraction. The inferior pulmonary ligament is divided, and the posterior mediastinum is inspected for extravasation of milky fluid. Any visible sources of chyle leakage can be controlled with clips or suture ligatures. In some cases, mass ligation of the thoracic duct at the level of the diaphragm, incorporating all of the soft tissue between the aorta and the azygos vein, may be required.

Left-side leaks can be difficult to manage. The subcarinal area is typically involved; this is the level at which the thoracic duct crosses over from the right. Exploration should begin on the left side. If the leak cannot be visualized, a right-side approach may be necessary to control the thoracic duct as it first enters the chest.

Anastomotic Leakage

The consequences of anastomotic complications after esophagectomy vary considerably in severity, depending on their location and cause. The cervical anastomotic leaks that may develop after transhiatal esophagectomy are generally simple to treat. Leaks in the early postoperative period are usually related to technical factors (e.g., excessive tension across the anastomosis). A nonviable stomach may not give rise to obvious signs; thus, any possibility of ischemia in the transposed stomach must be addressed promptly. Tachycardia, confusion, leukocytosis, cervical wound drainage, and neck tenderness may or may not be present.

The morbidity of an open cervical wound is not high—it is certainly lower than that of an untreated leak. Accordingly, any clinical suspicion of a leak should prompt a diagnostic contrast swallow study using dilute barium. Large leaks are manifested as persistent collections of contrast material outside the esophagus. Although such leaks rarely extend into the pleural space, any fluid in the chest must be drained so that its nature can be determined. The neck wound is opened by removing the sutures and performing gentle digital exploration of the prevertebral space behind the esophagus as the finger is advanced into the mediastinum; this is usually done at the bedside and requires little, if any, patient sedation.

Saline-moistened gauze packing is changed three or four times a day. Prolonged or copious cervical drainage may call for supplemental deep wound aspiration with a Yankauer suction handle. Administering water orally during aspiration facilitates removal of any necrotic debris. A fetid, malodorous breath associated with sanguineous discharge from the nasogastric tube and purulent fluid in the opened neck incision are ominous signs that should prompt early esophagoscopy. Diffuse mucosal ischemia may indicate the presence of a nonviable stomach; reoperation with completion gastrectomy and proximal esophagostomy is required to treat this rare catastrophic complication.

Generally, leaks that occur more than 7 days after operation are small and are related to some degree of late ischemic disruption along the anastomosis. They can usually be managed by opening the cervical wound at the bedside and packing the site with gauze. Oral diet is advanced as tolerated. It

may be noted that the volume of the leak is markedly greater or less depending on the position of the head during swallowing. Accordingly, before discharge, patients are taught how to temporarily adjust their swallowing and how to manage their dressing changes. Applying gentle pressure to the neck wound and turning the head to the left may help the patient ingest liquids with minimal soiling of the open neck incision. Dysphagia, even with an opened neck incision, should be treated by passing tapered esophageal dilators orally between 2 and 4 weeks after surgery. When a bougie at least 48 French in caliber can be passed through the anastomosis, the patient can usually swallow comfortably. The size of the leak often decreases after dilation as food is allowed to proceed preferentially into the stomach. To maximize the diameter of the anastomosis and reduce the likelihood of a symptomatic stricture, subsequent dilations should be scheduled at 2-week intervals for the next few months.

When a routine predischarge barium swallow after transhiatal esophagectomy raises the possibility of an anastomotic leak in an asymptomatic patient, the question arises of whether the wound should be opened at all. For small, contained leaks associated with preferential flow of contrast material into the stomach, observation alone may suffice in selected cases. Patients must be closely watched for fever or other signs of major infection. Given the quite low morbidity of cervical wound exploration, the surgeon should not hesitate to drain the neck if the patient's condition changes.

The incidence of anastomotic leakage is low after Ivor Lewis resection, but the consequences are significant. Leaks presenting early in the postoperative period are usually related to technical problems and are difficult to manage; those presenting later are generally related to some degree of ischemic tissue loss. Patients who have received radiation therapy or are nutritionally depleted may be especially vulnerable to problems with anastomotic healing. A contrast swallow with dilute barium is the best method of evaluating the anastomosis. Leaks may be manifested either as a free flow of contrast into the pleural space or as a contained fluid collection.

Small leaks that drain immediately into properly placed thoracostomy tubes can usually be managed by giving antibiotics and withholding oral intake. Local control of infection generally results in spontaneous healing. Anastomotic disruptions that are large or are associated with a major pleural collection typically necessitate open drainage with decortication; percutaneous drainage may be considered as a preliminary approach in selected patients. Persistent soiling of the mediastinum and the pleural space is fatal if untreated.

Early esophagoscopy is strongly advised to evaluate the viability of the gastric remnant. Ischemic necrosis of the stomach necessitates reexploration, decortication, takedown of the anastomosis, gastric débridement, return of any viable stomach into the abdomen, closure of the hiatus, and proximal diversion with a cervical esophagostomy. Repair or revision of the anastomosis in an infected field is certain to fail and should never be considered. In certain cases, diversion via a cervical esophagostomy and a completion gastrectomy may be required.

Late Complications

At every postoperative visit, symptoms of reflux, regurgitation, dumping, poor gastric emptying, and dysphagia must be

specifically sought: these are the major quality-of-life issues for postesophagectomy patients.⁴ Reflux and regurgitation may complicate any form of alimentary reconstruction after esophagectomy, although cervical anastomoses are less likely to be associated with symptomatic reflux than intrathoracic anastomoses are. Reflux symptoms generally respond to dietary modifications, such as smaller and more frequent meals. Regurgitation is usually related to the supine position and thus tends to be worse at night; elevating the bed and avoiding late meals may suffice for symptom control. Dumping is exacerbated by foods with high fat or sugar content. Dysphagia may be related to narrowing at the anastomosis or, in rare instances, to poor emptying of the transposed stomach. Anastomotic strictures are most commonly encountered as a sequel to a postoperative leak. There may be excessive scarring at the anastomosis, associated with local distortion or angulation. Specific tests for gastric atony include nuclear medicine gastric emptying studies using radiolabeled food. A simple barium swallow may indicate an incomplete pyloromyotomy as a cause of poor gastric emptying; balloon dilation often corrects this problem.

Any form of anastomotic leak will increase the incidence of late stricture. Dysphagia may be treated by means of progressive dilation with Maloney bougies. This procedure is performed in the outpatient clinic and often does not require sedation or any other special patient preparation. Complications are rare if due care is exercised during the procedure. As noted [see Transthoracic Hiatal Hernia Repair, Preoperative Evaluation, Dilation, *above*], it is essential that the caliber of the dilators be increased gradually and that little or no force be applied in advancing them. The appearance of blood on a withdrawn dilator signals a breach of the mucosa; further dilation should be done cautiously lest a transmural injury results. Comfortable swallowing, of liquids at least, is usually achieved after the successful passage of a 48 French bougie. It is preferable, however, to advance dilation until at least a 54 French bougie can be passed with ease. For late strictures that are particularly difficult to dilate, endoscopic examination and histologic evaluation may be required to rule out a recurrent tumor. CT of the chest should also be performed whenever there is unexplained weight loss or fatigue late after esophagectomy.

The Savary system of wire-guided dilators has been particularly helpful in the management of tight or eccentric strictures. Patients are generally treated in the endoscopy suite. Temporary sedation with intravenous fentanyl and midazolam is required. Fluoroscopy can be used to confirm proper placement of a flexible-tip wire across the stricture. Serial wire-guided dilation can then be performed with confidence and increased patient safety.

OUTCOME EVALUATION

Transhiatal Esophagectomy

A 2001 study from the University of Michigan presented data on 1,085 patients who underwent transhiatal esophagectomy without thoracotomy, of whom 74% had carcinoma and 26% had nonmalignant disease.⁵ Transhiatal esophagectomy was completed in 98.6% of the patients; the remaining 1.4% were converted to a transthoracic esophagectomy as a result of either thoracic esophageal fixation or bleeding.

Previous chemotherapy or radiation therapy did not preclude performance of a transhiatal esophagectomy. Nine patients experienced inordinate intraoperative blood loss; three died as a result. The overall hospital mortality was 4%. The overall 5-year survival rate for patients undergoing transhiatal esophagectomy is approximately 20% for adenocarcinoma of the cardia and the esophagus and 30% for squamous cell carcinoma of the esophagus.

The stapled anastomosis described earlier [see Operative Technique, Transhiatal Esophagectomy, Step 8, *above*] reflects numerous refinements introduced at the University of Michigan. The endoscopic GIA stapler has a low-profile head that is ideally suited to the tight confines of the neck, enabling the surgeon to fashion a widely patent side-to-side functional EEA with three rows of staples along the back wall. The rate of anastomotic stricture is markedly lower with this anastomosis than with a totally handsewn anastomosis. As regards postoperative function, stomach interposition through the posterior mediastinum after transhiatal esophagectomy is associated with low rates of aspiration and regurgitation. Esophageal reflux and esophagitis—commonly seen with intrathoracic esophagogastric anastomoses—are usually not clinically significant problems with this approach. Patients are advised to elevate the head of their bed and to continue taking acid blockers for about 3 months after the operation. Approximately one third will require esophageal dilation for dysphagia after the operation. Some 7 to 10% experience postvagotomy dumping symptoms, which, in most cases, can be controlled by simply avoiding high-carbohydrate foods and dairy products.

Ivor Lewis Esophagectomy

Ivor Lewis esophagectomy is associated with anastomotic leakage rates and operative mortalities of less than 3%.^{3,6} Approximately 5% of patients will require anastomotic dilation. Again, patients are advised to elevate the head of the bed and to continue taking acid blockers if they have any

reflux symptoms. In some patients, the gastric interposition rotates into the right posterolateral thoracic gutter, resulting in postprandial gastric tension and rendering them more susceptible to aspiration. Compared to transhiatal esophagectomy, extended transthoracic esophagectomy is associated with higher pulmonary morbidity but no difference in operative mortality or in 5-year survival. A post hoc subset analysis did suggest a survival advantage of transthoracic resection with one to eight positive lymph nodes.^{7,8}

Three-Hole Esophagectomy

Three-hole esophagectomy is also associated with low anastomotic leak rates and mortality similar to Ivor Lewis esophagectomy.⁹ Again, patients are advised to elevate the head of the bed and to continue taking acid blockers if they have any reflux symptoms. In some patients, the gastric interposition rotates into the right posterolateral thoracic gutter, resulting in postprandial gastric tension and rendering them more susceptible to aspiration. A special note should be made that cervical leaks with a three-hole esophagectomy can be more problematic than with a transhiatal esophagectomy presumably because of the wide opening of the mediastinum resulting in a greater tendency of leaks to track down into the mediastinum.

Left Thoracoabdominal Esophagogastrectomy

Left thoracoabdominal esophagogastrectomy is also associated with anastomotic leakage rates and operative mortalities of less than 3%.^{3,10} Approximately 5% of patients will require esophageal dilation. Reconstructions involving anastomosis of the distal stomach to the esophagus are associated with a higher incidence of bile gastritis and esophagitis. Of all the operations we have described, this one results in the lowest postoperative quality of life. Accordingly, most surgeons prefer to carry out a total gastrectomy. Swallowing is restored with a Roux-en-Y jejunal interposition.

Financial Disclosures: None Reported.

8 MINIMALLY INVASIVE ESOPHAGEAL PROCEDURES

Francesco Palazzo, MD, Piero M. Fisichella, MD, Marco G. Patti, MD, FACS

The development of laparoscopic surgery over the past 20 years has caused a significant shift in the treatment of benign esophageal diseases.

In the first part of the 1990s, it became clear that treatment of benign esophageal disorders with minimally invasive procedures yielded results comparable to those of treatment with traditional operations while causing minimal postoperative discomfort, reducing the duration of hospitalization, shortening recovery time, and permitting earlier return to work.^{1,2} Consequently, minimally invasive surgery was increasingly considered as first-line treatment for achalasia, and laparoscopic fundoplication was considered more readily and at an earlier stage in the management of gastroesophageal reflux disease (GERD).

Since then, minimally invasive esophageal procedures have continued to evolve, thanks to better instrumentation and improved surgical expertise. In addition, with greater experience and longer follow-up, it has become possible to analyze techniques and their results more rigorously. For instance, whereas a few years ago a left thoracoscopic Heller myotomy was considered the procedure of choice for achalasia, the current procedure of choice is a laparoscopic Heller myotomy with partial fundoplication, which has proved to be better at relieving dysphagia and controlling postoperative reflux.³⁻⁶ Similarly, whereas total fundoplication and partial fundoplication were initially considered equally effective in treating GERD,⁷ total fundoplication is currently used even when peristalsis is weak. Long-term results have, in fact, shown that although the dysphagia rates of the two procedures are similar, total fundoplication achieves better control of reflux than partial fundoplication.⁸

In this chapter, we focus on minimally invasive approaches to the treatment of GERD and esophageal motility disorders. The standard open counterparts of these operations are described elsewhere [see 4:7 *Open Esophageal Procedures*].

Laparoscopic Nissen Fundoplication

PREOPERATIVE EVALUATION

All patients who are candidates for a laparoscopic fundoplication should undergo a preoperative evaluation that includes the following: (1) symptomatic evaluation, (2) an upper gastrointestinal (GI) series, (3) endoscopy, (4) esophageal manometry, and (5) ambulatory pH monitoring.

Symptomatic Evaluation

The presence of both typical symptoms (heartburn, regurgitation, and dysphagia) and atypical symptoms of GERD (cough, asthma, chest pain, dental erosions, and hoarseness)

should be investigated, and symptoms should be graded with respect to their intensity both before and after the operation. Nonetheless, a diagnosis of GERD should never be based solely on symptomatic evaluation. Some assert that the diagnosis can be made reliably from the clinical history,⁹ so that a complaint of heartburn should lead to the presumption that acid reflux is present; however, testing of this diagnostic strategy demonstrates that symptoms are far less sensitive and specific than is usually believed.¹⁰ For instance, a study from the University of California, San Francisco (UCSF), found that of 822 consecutive patients referred for esophageal function tests with a clinical diagnosis of GERD (based on symptoms and endoscopic findings), only 70% had abnormal reflux on pH monitoring.¹¹ Heartburn and regurgitation were no more frequent in patients who had genuine reflux than in those who did not; thus, symptomatic evaluation, by itself, could not distinguish between the two groups.

The response to proton pump inhibitors (PPIs) is a better predictor of abnormal reflux. For example, in the UCSF study just cited, 75% of patients with GERD reported a good or excellent response to PPIs, compared with only 26% of patients without GERD.¹¹ Similarly, a study involving multivariate analysis of factors predicting outcome after laparoscopic fundoplication identified a clinical response to acid suppression therapy as one of three factors predictive of a successful outcome, the other two being an abnormal 24-hour pH score and the presence of a typical primary symptom (e.g., heartburn).¹² In addition, a 2007 report found that patients with a body mass index (BMI) of 35 kg/m² or greater experienced higher failure rates after laparoscopic Nissen fundoplication.¹³ These data support the theory that GERD in morbidly obese patients has a different pathophysiology and may warrant a different therapeutic approach (e.g., laparoscopic Roux-en-Y gastric bypass [see 5:7 *Surgical Treatment of Morbid Obesity*]).¹⁴

Upper Gastrointestinal Series

An upper GI series is useful for diagnosing and characterizing an existing hiatal hernia. The size of the hiatal hernia helps predict how difficult it will be to reduce the esophago-gastric junction below the diaphragm. In addition, large hiatal hernias are associated with more severe disturbances of esophageal peristalsis and esophageal acid clearance.¹⁵ Esophagograms are also useful for determining the location, shape, and size of a stricture and for suggesting the presence of a short esophagus.

Endoscopy

Endoscopy is typically the first test performed to confirm a symptom-based diagnosis of GERD. This approach has two

pitfalls. First, even though the goal of endoscopy is to assess the mucosal damage caused by reflux, mucosal changes are absent in about 50% of GERD patients.¹¹ Second, major interobserver variations have been reported with esophageal endoscopy, particularly for low-grade esophagitis.¹⁶ In one study, for instance, 60 (24%) of 247 patients with negative results on pH monitoring had been diagnosed as having grade I or II esophagitis.¹¹ Endoscopy is also valuable for excluding gastric and duodenal pathologic conditions and detecting the presence of Barrett's esophagus.

Esophageal Manometry

Esophageal manometry provides useful information about the motor function of the esophagus by determining the length and resting pressure of the lower esophageal sphincter (LES) and assessing the quality (i.e., the amplitude and propagation) of esophageal peristalsis. In addition, it allows proper placement of the pH probe for ambulatory pH monitoring (5 cm above the upper border of the LES).

Ambulatory pH Monitoring

Ambulatory pH monitoring is the most reliable test for the diagnosis of GERD, with a sensitivity and specificity of about 92%.¹⁷ It is of key importance in the workup for the following four reasons.

1. It determines whether abnormal reflux is present. In the UCSF study mentioned earlier,¹¹ pH monitoring yielded normal results in 30% of patients with a clinical diagnosis of GERD, thereby obviating the continuation of inappropriate and expensive drugs (e.g., PPIs) or the performance of a fundoplication. In addition, pH monitoring prompted further investigation that in a number of cases pointed to other diseases (e.g., cholelithiasis and irritable bowel syndrome).
2. It establishes a temporal correlation between symptoms and episodes of reflux. Such a correlation is particularly important when atypical GERD symptoms (e.g., cough and chest pain) are present because 50% of these patients experience no heartburn and 50% do not have esophagitis on endoscopy.¹⁸
3. It allows staging on the basis of disease severity. Specifically, esophageal manometry and pH monitoring identify a subgroup of patients characterized by worse esophageal motor function (manifested by a defective LES or by abnormal esophageal peristalsis), more acid reflux in the distal and proximal esophagus, and slower acid clearance. These patients more frequently have Barrett metaplasia and experience respiratory symptoms; thus, they might benefit from early antireflux surgery.¹⁹
4. It provides baseline data that may prove useful postoperatively if symptoms do not respond to the procedure.

Multichannel Intraluminal Impedance and pH Combined multichannel intraluminal impedance and pH testing (MII-pH) has the ability to detect episodes of reflux, regardless of the pH of the refluxate, by identifying changes induced by the presence of a bolus in the esophagus; the episodes are then simply classified as acid or nonacid on the basis of concomitantly recorded pH values. Studies of healthy persons have demonstrated that MII-pH possesses increased sensitivity

and specificity in detecting and characterizing gastroesophageal reflux, and the results have been shown to be highly reproducible.²⁰

Although this technology is still not widely available, it has already been demonstrated to be useful in the workup of patients with GERD refractory to PPIs and patients with respiratory symptoms of unknown origin.²¹

OPERATIVE PLANNING

The patient is placed under general anesthesia and intubated with a single-lumen endotracheal tube. Abdominal wall relaxation is ensured by the administration of a nondepolarizing muscle relaxant, the action of which is rapidly reversed at the end of the operation. Adequate muscle relaxation is essential because increased abdominal wall compliance allows increased pneumoperitoneum, which yields better exposure. An orogastric tube is inserted at the beginning of the operation to keep the stomach decompressed; it is removed at the end of the procedure.

The patient is placed in a steep reverse Trendelenburg position, with the legs extended on stirrups. The surgeon stands between the patient's legs. To keep the patient from sliding as a result of the steep position used during the operation, a bean bag is inflated under the patient, and the knees are flexed only 20° to 30°. A Foley catheter is inserted at the beginning of the procedure and usually is removed at the end. Because increased abdominal pressure from pneumoperitoneum and the steep reverse Trendelenburg position decrease venous return, pneumatic compression stockings are always used as prophylaxis against deep vein thrombosis.

The equipment required for a laparoscopic Nissen fundoplication includes five 10 mm trocars, a 30° laparoscope, a hook cautery, and various other instruments [see Table 1]. In addition, we use a three-chip camera system that is separate from the laparoscope.

OPERATIVE TECHNIQUE

A total fundoplication is the procedure of choice. A partial fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, *below*] is performed only when peristalsis is absent.^{22,23} The operation may be divided into nine key steps as follows.

Table 1 Instrumentation for Laparoscopic Nissen Fundoplication

Five 10 mm trocars
30° scope
Graspers and needle holder
Babcock clamp
L-shaped hook cautery with suction-irrigation capacity
Scissors
Laparoscopic clip applier
LigasSure™ Vessel Sealing System*
Fan retractor
Endo Stitch device†
Penrose drain
2-0 silk sutures
56 French esophageal bougie

* (Valleylab, Boulder, CO)

† (Autosuture, Norwalk, CT)

Step 1: Placement of Trocars

Five 10 mm trocars are used for the operation [see Figure 1]. Port A is placed about 14 cm below the xiphoid process; it can also be placed slightly (2 to 3 cm) to the left of the midline to be in line with the hiatus. This port is used for insertion of the scope. Port B is placed at the same level as port A but in the left midclavicular line. It is used for insertion of the Babcock clamp; insertion of a grasper to hold the Penrose drain once it is in place surrounding the esophagus; or insertion of an instrument to take down the short gastric vessels. Port C is placed at the same level as the previous two ports but in the right midclavicular line. It is used for insertion of the fan retractor, the purpose of which is to lift the lateral segment of the left hemiliver and expose the esophagogastric junction. We do not divide the left triangular ligament. The fan retractor can be held in place by a self-retaining system fixed to the operating table. Ports D and E are placed as high as possible under the costal margin and about 5 to 6 cm to the right and the left of the midline so that they are about 15 cm from the esophageal hiatus; in addition, they should be placed so that their axes form an angle of 60° to 120°. These ports are used for insertion of the graspers, the electrocautery, and the suturing instruments.

Troubleshooting If the ports are placed too low in the abdomen, the operation is made more difficult. If port C is too low, the fan retractor will not retract the left lateral section of the liver well, and the esophagogastric junction will not be properly exposed. If port B is too low, the Babcock clamp will not reach the esophagogastric junction, and when the instrument used to

take down the short gastric vessels is placed through the same port, it will not reach the upper short gastric vessels. If ports D and E are too low, the dissection at the beginning of the procedure and the suturing at the end are problematic.

Other mistakes of positioning must be avoided as well. Port C must not be placed too medially, because the fan retractor may clash with the left-hand instrument; the gallbladder fossa is a good landmark for positioning this port. Port A must be placed with extreme caution in the supraumbilical area: its insertion site is just above the aorta, close to its bifurcation. Accordingly, we initially inflate the abdomen to a pressure of 18 mm Hg just for placement of port A; increasing the distance between the abdominal wall and the aorta reduces the risk of aortic injury. We also recommend directing the port toward the coccyx. Once port A is in place, the intraperitoneal pressure is reduced to 15 mm Hg. A Hasson cannula can be used in this location, particularly if the patient has already had one or more midline incisions. Maintaining the proper angle (60° to 120°) between the axes of the two suturing instruments inserted through ports D and E is also important: if the angle is smaller, the instruments will cover part of the operating field, whereas if it is larger, depth perception may be impaired. Finally, if a trocar is not in the ideal position, it is better to insert another one than to operate through an inconveniently placed port.

If the surgeon spears the epigastric vessels with a trocar, bleeding will occur, in which case we prefer to ligate the vessel under laparoscopic guidance. We favor the Carter-Thomason CloseSure System (Inlet Medical, Inc., Eden Prairie, MN) to ligate the vessel securely with 0 absorbable suture. Once hemostasis is obtained, the surgeon simply repositions the trocar away from the vessels.

Step 2: Division of Gastrohepatic Ligament; Identification of Right Crus of Diaphragm and Posterior Vagus Nerve

Once the ports are in place, the gastrohepatic ligament is divided. Dissection begins above the caudate lobe (segments 1 and 9) of the liver, where this ligament usually is very thin, and continues toward the diaphragm until the right crus is identified. The crus is then separated from the right side of the esophagus by blunt dissection, and the posterior vagus nerve is identified. The right crus is dissected inferiorly toward the junction with the left crus.

Troubleshooting An accessory left hepatic artery originating from the left gastric artery is frequently encountered in the gastrohepatic ligament. If this vessel creates problems of exposure, it may be divided; in our experience, doing so has not caused problems. In dissecting the right crus from the esophagus, the electrocautery should be used with particular caution. Because the monopolar current tends to spread laterally, the posterior vagus nerve may sustain damage simply from being in proximity to the device, even when there is no direct contact. A better alternative is to use a bipolar instrument.

Step 3: Division of Peritoneum and Phrenoesophageal Membrane above Esophagus; Identification of Left Crus of Diaphragm and Anterior Vagus Nerve

The peritoneum and the phrenoesophageal membrane above the esophagus are divided with the electrocautery, and the anterior vagus nerve is identified. The left crus of the diaphragm is dissected downward toward the junction with the right crus.

Figure 1 Laparoscopic Nissen fundoplication. Illustrated is the recommended placement of the trocars.

Troubleshooting Care must be taken not to damage the anterior vagus nerve or the esophageal wall. To this end, the nerve should be left attached to the esophageal wall, and the peritoneum and the phrenoesophageal membrane should be lifted from the wall by blunt dissection before they are divided.

Step 4: Division of Short Gastric Vessels

The 5 mm laparoscopic LigaSure Vessel Sealing System (Valleylab, Boulder, CO) is introduced through port B. A grasper is introduced by the surgeon through port D, and an assistant applies traction on the greater curvature of the stomach through port E. Dissection begins at the level of the middle portion of the gastric body and continues upward until the most proximal short gastric vessel is divided.

Troubleshooting There are two problems to watch for during this part of the procedure: (1) bleeding, either from the short gastric vessels or from the spleen, and (2) damage to the gastric wall.

Bleeding from the short gastric vessels is usually caused by excessive traction or by division of a vessel that is not completely coagulated. Vessels up to 5 mm in diameter can be taken down with the LigaSure device. Damage to the gastric wall can be caused by a burn from the electrocautery used to dissect between vessels or by traction applied with the graspers or the Babcock clamp.

Step 5: Creation of Window between Gastric Fundus, Esophagus, and Diaphragmatic Crura; Placement of Penrose Drain around Esophagus

The esophagus is retracted upward with a Babcock clamp applied at the level of the esophagogastric junction. By means of blunt and sharp dissection, a window is created under the esophagus between the gastric fundus, the esophagus, and the left pillar of the crus. The window is enlarged with the LigaSure device, and a Penrose drain is passed around the esophagus. This drain is then used for traction instead of the Babcock clamp to reduce the risk of damage to the gastric wall.

Troubleshooting The two main problems to watch for during this part of the procedure are (1) creation of a left pneumothorax and (2) perforation of the gastric fundus.

A left pneumothorax is usually caused by dissection done above the left pillar of the crus in the mediastinum rather than between the crus and the gastric fundus. This problem can be avoided by properly dissecting and identifying the left pillar of the crus.

Perforation of the gastric fundus is usually caused by pushing a blunt instrument under the esophagus and below the left pillar without having done enough dissection. Care must be exercised in taking down small vessels from the fundus when the area behind the esophagus is approached from the right: the anatomy is not as clear from this viewpoint, and perforation can easily occur. Sometimes, perforation is caused by the use of a monopolar electrocautery for dissection. An electrocautery burn can go unrecognized during dissection and manifest itself in the form of a leak during the first 48 hours after operation.

Step 6: Closure of Crura

The diaphragmatic crura are closed with interrupted 2-0 silk sutures on an Endo Stitch device (Autosuture, Norwalk,

CT); the sutures are tied intracorporeally. Exposure is provided by retracting the esophagus upward and toward the patient's left with the Penrose drain. The lens of the 30° laparoscope is angled slightly to the left by moving the light cable of the scope to the patient's right. The first stitch should be placed just above the junction of the two pillars. Additional stitches are placed 1 cm apart, and a space of about 1 cm is left between the uppermost stitch and the esophagus.

Troubleshooting Care must be taken not to spear esophageal wall with the needle. So as not to limit the space available for suturing, the bougie is not placed inside the esophagus during this part of the procedure.

Step 7: Insertion of Bougie into Esophagus and through Esophagogastric Junction

The esophageal stethoscope and the orogastric tube are removed, and a 56 French bougie is inserted by the anesthesiologist and passed through the esophagogastric junction under laparoscopic vision. The crura must be snug around the esophagus but not too tight: a closed grasper should slide easily between the esophagus and the crura.

Troubleshooting The most worrisome complication during this step is perforation of the esophagus. This can be prevented by lubricating the bougie and instructing the anesthesiologist to advance the bougie slowly and to stop if any resistance is encountered. In addition, it is essential to remove any instruments from the esophagogastric junction and to open the Penrose drain; these measures prevent the creation of an angle between the stomach and the esophagus, which can increase the likelihood of perforation. The position of the bougie can be confirmed by pressing with a grasper over the esophagus, which will feel full when the bougie is in place.

Step 8: Wrapping of Gastric Fundus around Lower Esophagus

The gastric fundus is gently pulled under the esophagus with the graspers. The left and right sides of the fundus are wrapped above the fat pad (which lies above the esophagogastric junction) and held together in place with a Babcock clamp introduced through port B. (The Penrose drain should be removed at this point because it is in the way.) Usually, three 2-0 silk sutures are used to secure the two ends of the wrap to each other. The stitches do not include the esophagus. Two coronal stitches are then placed between the top of the wrap and the esophagus, one on the right and one on the left. Finally, one additional suture is placed between the right side of the wrap and the closed crura.

To avoid the risk of injuring the inferior vena cava at the beginning of the dissection, some surgeons use a different method—the so-called left crus approach.²² In this approach, the operation begins with identification of the left crus of the diaphragm and division of the peritoneum and the phrenoesophageal membrane overlying it. The next step is division of the short gastric vessels, starting midway along the greater curvature of the stomach and continuing upward to join the area of the previous dissection. When the fundus has been thoroughly mobilized, the peritoneum is divided from the left to the right crus, and the right crus is dissected downward to expose the junction of the right and left crura. With this technique, the vena cava is never at risk. In addition, the branches of the anterior vagus nerve and

the left gastric artery are less exposed to danger. This technique can be very useful, particularly for management of very large paraesophageal hernias and for second antireflux operations [see Reoperation for GERD, *below*].

Troubleshooting To determine whether the wrap is going to be floppy, the surgeon must deliver the fundus under the esophagus, making sure that the origins of the short gastric vessels that have been transected are visible. Essentially, the posterior wall of the fundus is being used for the wrap. If the wrap remains to the right of the esophagus without retracting back to the left, then it is floppy, and suturing can proceed. If not, the surgeon must make sure that the upper short gastric vessels have been transected and the posterior dissection completed. If tension is still present after these maneuvers, it is probably best to perform a partial wrap [see Laparoscopic Partial (Guarner) Fundoplication, *below*].

Damage to the gastric wall may occur during the delivery of the fundus. Atraumatic graspers must be used, and the gastric fundus must be pulled gently and passed from one grasper to the other. Sometimes, it is helpful to push the gastric fundus under the esophagus from the left. The wrap should measure no more than 2 to 2.5 cm in length and, as noted, should be done with no more than three sutures. The first stitch is usually the lowest one; it must be placed just above the fat pad where the esophagogastric junction is thought to be.

If the anesthesiologist observes that peak airway pressure has increased (because of a pneumothorax) or that neck emphysema is present (because of pneumomediastinum), the pneumoperitoneum should be reduced from 15 mm Hg to 8 or 10 mm Hg until the end of the procedure. Pneumomediastinum tends to resolve without intervention within a few hours of the end of the procedure. Small pneumothoraces (usually on the left side) tend to resolve spontaneously, rendering insertion of a chest tube unnecessary. Larger pneumothoraces (> 20%), however, call for the insertion of a small (18 to 20 French) chest tube.

Step 9: Final Inspection, Removal of Instruments and Ports from Abdomen, and Closure of Port Sites

After hemostasis is obtained, the instruments and the ports are removed from the abdomen under direct vision. We usually close all port sites with 0 absorbable suture material using the Carter-Thomason CloseSure System.

Troubleshooting If any areas of oozing were observed, they should be irrigated and dried with sponges rolled into a cigarettelike shape before the ports are removed. In addition, if some grounds for concern remain, the oozing areas should be examined after the pneumoperitoneum is decreased to 7 to 8 mm Hg to abolish the tamponading effect exerted by the high intra-abdominal pressure.

All the ports should be removed from the abdomen under direct vision so that any bleeding from the abdominal wall can be readily detected. Such bleeding is easily controlled, either from inside or from outside.

COMPLICATIONS

A feared complication of laparoscopic Nissen fundoplication is esophageal or gastric perforation, which may result either from traction applied with the Babcock clamp or a grasper to the esophagus or the stomach (particularly when the stomach is

pulled under the esophagus) or from inadvertent electrocautery burns during any part of the dissection. A leak will manifest itself during the first 48 hours. Peritoneal signs will be noted if the spillage is limited to the abdomen; shortness of breath and a pleural effusion will be noted if spillage also occurs in the chest. The site of the leak should always be confirmed by a contrast study with barium or a water-soluble contrast agent. Optimal management consists of laparotomy and direct repair. If a perforation is detected intra-operatively, it may be closed laparoscopically.

Almost every patient experiences some degree of dysphagia postoperatively. This problem usually resolves after 4 to 6 weeks, during which period patients receive pain medications in an elixir form and are advised to avoid eating meat and bread. If, however, dysphagia persists beyond this period, one or more of the following causes is responsible.

1. A wrap that is too tight or too long (i.e., > 2.5 cm).²⁴
2. Lateral torsion with corkscrew effect. If the wrap rotates to the right (because of tension from intact short gastric vessels or because the fundus is small), a corkscrew effect is created.
3. A wrap made with the body of the stomach rather than the fundus. The relaxation of the LES and the gastric fundus is controlled by vasoactive intestinal polypeptide and nitric oxide^{25,26}; after fundoplication, the two structures relax simultaneously with swallowing. If part of the body of the stomach rather than the fundus is used for the wrap, it will not relax as the LES does on arrival of the food bolus.
4. Choice of the wrong procedure. In patients who have severely abnormal esophageal peristalsis (as in end-stage connective tissue disorders), a partial wrap is preferable. A 360° wrap may cause postoperative dysphagia and gas bloat syndrome.

If the wrap slips into the chest, the patient may experience dysphagia and regurgitation. The diagnosis is confirmed by means of a barium swallow. This problem can be prevented by using coronal sutures and by ensuring that the crura are closed securely.

Paraesophageal hernia may occur if the crura have not been closed or if the closure is too loose. We believe that closure of the crura not only is essential for preventing paraesophageal hernia but also is important from a physiologic point of view, in that it acts synergistically with the LES against stress reflux. Sometimes, it is possible to reduce the stomach and close the crura laparoscopically. More often, however, because the crural opening is very tight and the gastric wall is edematous, laparoscopic repair is impossible and laparotomy is preferable.

POSTOPERATIVE CARE AND OUTCOME EVALUATION

Postoperative care and outcome evaluation of laparoscopic Nissen fundoplication are considered elsewhere in conjunction with the discussion of partial fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, Postoperative Care and Outcome Evaluation, *below*].

Laparoscopic Partial (Guarner) Fundoplication

PREOPERATIVE EVALUATION AND OPERATIVE PLANNING

Preoperative evaluation and operative planning are essentially the same for partial (Guarner) fundoplication as for Nissen

fundoplication. This operation should be performed only in patients with the most severe abnormalities of esophageal peristalsis: it is less effective than a 360° wrap for long-term control of reflux.⁸ In addition, laparoscopic partial fundoplication may be performed after laparoscopic Heller myotomy for achalasia [see Laparoscopic Heller Myotomy with Partial Fundoplication, below].²⁷

OPERATIVE TECHNIQUE

The first seven steps in a Guarner fundoplication are identical to the first seven in a Nissen fundoplication. The wrap, however, differs in that it extends around only 240° to 280° of the esophageal circumference. Once the gastric fundus is delivered under the esophagus, the two sides are not approximated over the esophagus. Instead, 80° to 120° of the anterior esophagus is left uncovered, and each of the two sides of the wrap (right and left) is separately affixed to the esophagus with three 2-0 silk sutures, with each stitch including the muscle layer of the esophageal wall. The remaining stitches (i.e., the coronal stitches and the stitch between the right side of the wrap and the closed crura) are identical to those placed in a Nissen fundoplication.

POSTOPERATIVE CARE

Currently, our average operating time for a laparoscopic fundoplication is approximately 2 hours. We start patients on a soft mechanical diet on the morning of postoperative day 1 and usually discharge them after 23 to 48 hours. The recovery time typically ranges from 10 to 14 days.

OUTCOME EVALUATION

The initial results of laparoscopic fundoplication obtained in the early 1990s indicated that the operation was effective in controlling reflux but that postoperative dysphagia occurred more often than had been anticipated.⁷ Many experts thought that this problem could be avoided by tailoring the fundoplication to the strength of esophageal peristalsis as measured by esophageal manometry.⁷ Accordingly, partial fundoplication (240°) was recommended for patients with impaired peristalsis, and total fundoplication (360°) was recommended for those with normal peristalsis. The short-term results of this tailored approach were promising.⁷ Gradually, however, it became evident that a partial fundoplication was not as durable as a total fundoplication⁸ and that a total fundoplication was not associated with a higher incidence of postoperative dysphagia even in patients with weak peristalsis.^{28,29}

These findings suggest that the initial problems with postoperative dysphagia were primarily attributable to unknown technical factors that were largely eliminated from the procedure as surgeons garnered more experience with it. As a result, total fundoplication is currently considered the procedure of choice for patients with GERD, regardless of the strength of their esophageal peristalsis.

In a 2007 study, pre- and postoperative manometric results were reviewed in 71 patients who underwent laparoscopic fundoplication. Not only did LES pressure increase after the procedure, but distal esophageal amplitude also increased in patients with abnormal preoperative motility, with normalization of peristalsis occurring in the majority of patients.³⁰ A 2001 report found that 62% of fundoplication patients were using antireflux medications 10 years after the operation, a finding

that raised concerns about long-term durability of the procedure.³¹ This study has been criticized on the grounds that many of the patients were taking PPIs for reasons other than reflux symptoms and that the reflux status was not assessed by pH monitoring. A 2006 study aimed at critically assessing 10-year outcomes reported results from 100 consecutive patients after complete and partial fundoplication.³² In this series, the rate of symptomatic control of reflux symptoms at 5 and 10 years was 90%, with fewer than 10% of patients using antacid medications at 10 years; only one patient required reintervention for persistent dysphagia. Similar results were documented in subsequent studies,^{33,34} confirming laparoscopic Nissen fundoplication as an effective long-term treatment for GERD.

Laparoscopic Heller Myotomy with Partial Fundoplication

Minimally invasive surgical procedures for primary esophageal motility disorders (achalasia, diffuse esophageal spasm [DES], nutcracker esophagus [NE] and hypertensive LES [H-LES]) yield results that are comparable to those of open procedures but are associated with less postoperative pain and with a shorter recovery time.³⁵ Today, laparoscopic Heller myotomy with partial fundoplication has supplanted left thoracoscopic myotomy as the procedure of choice for esophageal achalasia.³⁻⁶ Long-term studies demonstrated that even though left thoracoscopic myotomy led to resolution of dysphagia in about 85% to 90% of patients, it had the following four drawbacks.

1. Gastroesophageal reflux developed postoperatively in about 60% of patients because no fundoplication was performed in conjunction with the myotomy.³ With the laparoscopic approach, in contrast, a partial fundoplication can easily be performed, which prevents reflux in the majority of patients^{3,4} and corrects many instances of preexisting reflux arising from pneumatic dilatation.³ A prospective, randomized, double-blind clinical trial that compared Heller myotomy alone with Heller myotomy and Dor fundoplication clearly demonstrated that the addition of a fundoplication is essential: the incidence of postoperative reflux (as measured by pH monitoring) was 48% in patients who underwent myotomy alone but only 9% in those who underwent myotomy and Dor fundoplication.³⁶
2. The extension of the myotomy onto the gastric wall (clearly the most critical and challenging part of the operation) proved difficult because of poor exposure, with the consequent risk of a short myotomy and persistent dysphagia. With the laparoscopic approach, in contrast, excellent exposure of the esophagogastric junction is easily achieved, and the myotomy can be extended onto the gastric wall for about 2 to 2.5 cm.^{3,37}
3. Double-lumen endotracheal intubation and single-lung ventilation were required, with the patient in the right lateral decubitus position. In contrast, the setting for a laparoscopic myotomy (the same as that for a laparoscopic fundoplication) is much easier for the patient, the anesthesiologist, and the operating room personnel. In addition, most surgeons have by now acquired substantial experience with laparoscopic antireflux procedures and thus are more familiar and comfortable with laparoscopic exposure of the distal esophagus and the esophagogastric junction.

4. The average postoperative hospital stay was about 3 days because of the chest tube left in place at the time of the operation and the discomfort arising from the thoracic incisions. After a laparoscopic Heller myotomy, the hospital stay is only 1 or 2 days; there is no need for a chest tube, and patients are more comfortable.

Although there is now a consensus on the preferred treatment of achalasia, there is no such general agreement on the treatment of the remaining primary esophageal motility disorders (i.e., DES, NE, and H-LES). We reported our experience comparing thoracoscopic and laparoscopic approaches to these disorders and found (1) that laparoscopic myotomy was superior to thoracoscopic myotomy in relieving dysphagia in patients with DES and H-LES, and (2) that the two approaches yielded equally disappointing results with respect to relieving chest pain in patients with NE, the surgical treatment of which remains elusive.³⁸ These results support the view that laparoscopic Heller myotomy should be the standard surgical treatment for achalasia, DES, and H-LES. Accordingly, we would consider surgical intervention (laparoscopic Heller myotomy) in an NE patient only in an attempt at relieving severe dysphagia.

We no longer perform a long myotomy via a right thoracoscopic approach.

PREOPERATIVE EVALUATION

All candidates for a laparoscopic Heller myotomy should undergo a thorough and careful evaluation to establish the diagnosis and characterize the disease.³⁹

An upper GI series is useful. A characteristic so-called bird's beak is usually seen in patients with achalasia. A dilated, sigmoid esophagus may be present in patients with long-standing achalasia. A corkscrew esophagus is often seen in patients with diffuse esophageal spasm. Endoscopy is performed to rule out a tumor of the esophagogastric junction and gastroduodenal pathologic conditions.

Esophageal manometry is the key test for establishing the diagnosis of esophageal achalasia. The classic manometric findings are (1) absence of esophageal peristalsis and (2) an LES that fails to relax appropriately in response to swallowing.

Ambulatory pH monitoring should always be done in patients who have undergone pneumatic dilatation to rule out abnormal gastroesophageal reflux. In addition, pH monitoring should be performed postoperatively to detect abnormal reflux, which, if present, should be treated with acid-reducing medications.³⁹

In patients older than 60 years who have experienced the recent onset of dysphagia and excessive weight loss, secondary achalasia or pseudoachalasia from cancer of the esophagogastric junction should be ruled out. Endoscopic ultrasonography or computed tomography can help establish the diagnosis.⁴⁰

OPERATIVE PLANNING

Patient preparation (i.e., anesthesia, positioning, and instrumentation) is identical to that for laparoscopic fundoplication.

OPERATIVE TECHNIQUE

Many of the steps in a laparoscopic Heller myotomy are the same as the corresponding steps in a laparoscopic fundoplication. The ensuing description focuses on those steps that differ significantly.

Either a Dor or a Guarner fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, *above*] may be performed in conjunction with a Heller myotomy. The Dor fundoplication is an anterior 180° wrap. Its advantages are that (1) it does not require posterior dissection and the creation of a window between the esophagus, the stomach, and the left pillar of the crus; (2) it covers the exposed esophageal mucosa after completion of the myotomy; and (3) it is effective even in patients with GERD.⁴¹ Its main disadvantage is that achieving the proper geometry can be difficult, and a wrong configuration can lead to dysphagia even after a properly performed myotomy.⁴² The advantages of the Guarner fundoplication are that (1) it is easier to perform; (2) it keeps the edges of the myotomy well separated; and (3) it might be more effective than a Dor procedure in preventing reflux. Its main disadvantages are that (1) it requires more dissection for the creation of a posterior window, and (2) it leaves the esophageal mucosa exposed.

Steps 1 through 6

Steps 1, 2, 3, 4, 5, and 6 of a laparoscopic Heller myotomy are essentially identical to the first six steps of a laparoscopic fundoplication. Steps 5 and 6, however, are necessary only if a posterior partial fundoplication is to be performed. Care must be taken not to narrow the esophageal hiatus too much and push the esophagus anteriorly.

Step 7: Intraoperative Endoscopy

At the beginning of a surgeon's experience with laparoscopic Heller myotomy, intraoperative endoscopy is an important and helpful step; however, once the surgeon has gained adequate experience with this procedure and has become familiar with the relevant anatomy from a laparoscopic perspective, it may be omitted.

Troubleshooting The most worrisome complication during intraoperative endoscopy is perforation of the esophagus. This complication can be prevented by having the procedure done by an experienced endoscopist who is familiar with achalasia.

Step 8: Initiation of Myotomy and Entry into Submucosal Plane at Single Point

The fat pad is removed with the LigaSure device to provide clear exposure of the esophagogastric junction. A Babcock clamp is then applied over the junction, and the esophagus is pulled downward and to the left to expose the right side of the esophagus. The myotomy is performed at the 11 o'clock position. It is helpful to mark the surface of the esophagus along the line through which the myotomy will be carried out [see Figure 2]. The myotomy is started about 3 cm above the esophagogastric junction. Before it is extended upward and downward, the proper submucosal plane should be reached at a single point; in this way, the likelihood of subsequent mucosal perforation can be reduced.

Troubleshooting The myotomy should not be started close to the esophagogastric junction, because at this level the layers often are poorly defined, particularly if multiple dilatations or injections of botulinum toxin have been performed. At the preferred starting point, about 3 cm above the esophagogastric junction, the esophageal wall is usually normal. As a rule, we do

Figure 2 Laparoscopic Heller myotomy with partial fundoplication. The proposed myotomy line is marked on the surface of the esophagus.

Figure 3 Laparoscopic Heller myotomy with partial fundoplication. The myotomy is extended proximally and distally.

not open the entire longitudinal layer first and then the circular layer; we find it easier and safer to try to reach the submucosal plane at a single point and then move upward and downward from there. In the course of the myotomy, there is always some bleeding from the cut muscle fibers, particularly if the esophagus is dilated and the wall is very thick. After the source of the bleeding is identified, the electrocautery must be used with caution. The most troublesome bleeding comes from the submucosal veins encountered at the esophagogastric junction (which are usually large). In most instances, gentle compression is preferable to electrocautery. A sponge introduced through one of the ports facilitates the application of direct pressure.

Step 9: Proximal and Distal Extension of Myotomy

Once the mucosa has been exposed, the myotomy can safely be extended [see Figure 3]. Distally, it is extended for about 2 to 2.5 cm onto the gastric wall; proximally, it is extended for about 6 cm above the esophagogastric junction. Thus, the total length of the myotomy is typically about 8 to 8.5 cm [see Figure 4]. We find it useful to alternate between a dolphin-nose grasper and using a curved micrograsper during extension of the myotomy; this makes the dissection safer, in that it allows the muscle fibers to be separated from the mucosa before being transected.

Troubleshooting The course of the anterior vagus nerve must be identified before the myotomy is started. If this nerve crosses the line of the myotomy, it must be lifted away from the esophageal wall, and the muscle layers must then be cut under it. In addition, care must be taken not to injure the anterior

vagus nerve while removing the fat pad. Treatment with botulinum toxin occasionally results in fibrosis with scarring and loss of the normal anatomic planes; this occurs more frequently at the level of the esophagogastric junction.

If a perforation seems possible or likely, it should be sought as described earlier [see Step 7: Intraoperative Endoscopy, above]. Any perforation found should be repaired with 5-0 absorbable suture material, with interrupted sutures employed for a small perforation and a continuous suture for a larger one. When a perforation has occurred, an anterior fundoplication is usually chosen in preference to a posterior one because the stomach will offer further protection against a leak.

Step 10 (Dor Procedure): Anterior Partial Fundoplication

Two rows of sutures are placed. The first row (on the left side) comprises three stitches: the uppermost stitch incorporates the gastric fundus, the esophageal wall, and the left pillar of the crus [see Figure 5], and the other two incorporate only the gastric fundus and the left side of the esophageal wall [see Figure 6]. The gastric fundus is then folded over the myotomy, and the second row (also comprising three stitches) is placed on the right side between the fundus and the right side of the esophageal wall, with only the uppermost stitch incorporating the right pillar of the crus [see Figure 7 and Figure 8]. Finally, two additional stitches are placed between the anterior rim of the hiatus and the superior aspect of the fundoplication [see Figure 9]. These stitches remove any tension from the second row of sutures.

Figure 4 Laparoscopic Heller myotomy with partial fundoplication. The myotomy is approximately 8 cm long, extending distally for about 2 to 2.5 cm onto the gastric wall and proximally for about 6 cm above the esophagogastric junction.

Figure 6 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The second and third stitches in the first row incorporate only the fundus and the left side of the esophageal wall.

Figure 5 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The uppermost stitch in the first row incorporates the fundus, the esophageal wall, and the left pillar of the crus.

Figure 7 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The uppermost stitch in the second row incorporates the fundus, the esophageal wall, and the right crus.

Figure 8 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The second and third stitches in the second row incorporate only the fundus and the right side of the esophageal wall.

Figure 9 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). Two final stitches are placed between the superior portion of the wrap and the anterior rim of the hiatus.

Troubleshooting Efforts must be made to ensure that the fundoplication does not become a cause of postoperative dysphagia. Accordingly, we always take down the short gastric vessels, even though some authorities suggest that this step can be omitted.^{4,40} In addition, the gastric fundus rather than the body of the stomach should be used for the wrap, and only the uppermost stitch of the right row of sutures should incorporate the right pillar of the crus.⁴¹

Step 10 (Guarner Procedure): Posterior Partial Fundoplication

Alternatively, a posterior 220° fundoplication may be performed. The gastric fundus is delivered under the esophagus, and each side of the wrap (right and left) is attached to the esophageal wall, lateral to the myotomy, with three sutures [see Figure 10].

Step 11: Final Inspection and Removal of Instruments and Ports from Abdomen

Step 11 of a laparoscopic Heller myotomy is identical to step 9 of a laparoscopic Nissen fundoplication.

COMPLICATIONS

Delayed esophageal leakage, usually resulting from an electrocautery burn to the esophageal mucosa, may occur during the first 24 to 36 hours after operation. The characteristic signs and symptoms are chest pain, fever, and a pleural effusion on the chest x-ray. The diagnosis is confirmed by an esophagogram. Treatment options depend on the time of diagnosis and on the size and location of the leak. Early, small leaks can be repaired directly. If the site of the leak is high in the chest, a thoracotomy

Figure 10 Laparoscopic Heller myotomy with posterior partial fundoplication (Guarner procedure). Each side of the posterior 220° wrap is attached to the esophageal wall with three sutures.

is recommended; if the site is at the level of the esophagogastric junction, a laparotomy is preferable, and the stomach can be used to reinforce the repair. If the damage to the esophagus is too extensive to permit repair, an esophagectomy [see 4:7 *Open Esophageal Procedures*] is indicated.

Dysphagia may either persist after the operation or recur after a symptom-free interval. In either case, a complete workup is necessary, and treatment is individualized on the basis of the specific cause of dysphagia. Reoperation may be indicated [see Reoperation for Esophageal Achalasia, *below*].

Abnormal gastroesophageal reflux occurs in 7 to 20% of patients after operation.^{3,4} Because most patients are asymptomatic, it is essential to try to evaluate all patients postoperatively with manometry and prolonged pH monitoring. Reflux should be treated with acid-reducing medications.

POSTOPERATIVE CARE

We do not routinely obtain an esophagogram before initiating feeding. Patients are started on a soft mechanical diet on the morning of postoperative day 1, and this diet is continued for the rest of the first week. Patients are discharged after 24 to 48 hours and are able to resume regular activities in 7 to 14 days.

OUTCOME EVALUATION

The results obtained to date with laparoscopic Heller myotomy and partial fundoplication are excellent and are generally comparable to those obtained with the corresponding open surgical procedure: dysphagia is alleviated or eliminated in more than 90% of patients.^{3,6,42} These results have been confirmed in long-term follow-up outcome studies. One report from the University of Padua found that at a minimum of 6 years after surgical intervention, 85% of myotomy patients were satisfied.⁴³

In a 2008 report describing our experience with 113 patients treated for achalasia with laparoscopic Heller myotomy and Dor fundoplication, we found that at a median follow-up of 45 months (range, 7 months to 12.5 years), 80% experienced complete relief of dysphagia after the operation.⁴⁴ The remaining 20% required endoscopic dilatation, which was successful in 50% of the cases. We have observed a significant change in the treatment algorithm for this condition: gastroenterologists now typically refer these patients for surgical treatment before any other therapy has been instituted, reserving endoscopic dilatation for cases where operative treatment has failed.⁴⁵ Overall, combined treatment yields a success rate of about 90%.

Historically, the presence of a sigmoid-shaped esophagus has been considered a contraindication to performing a myotomy to treat longstanding achalasia, making esophagectomy the only option. In the study just mentioned,⁴⁴ we subdivided the patients according to the degree of esophageal dilatation and observed the responses to surgery in the various groups. Even in those cases where the esophageal diameter exceeded 6 cm and the esophagus was sigmoid, the outcomes of laparoscopic myotomy were not significantly different.⁴⁴

Left Thoracoscopic Myotomy

Currently, we would consider a left thoracoscopic myotomy for patients in whom multiple previous abdominal procedures (done to treat other diseases) would preclude a laparoscopic approach.

PREOPERATIVE EVALUATION

Preoperative evaluation is essentially the same as that for laparoscopic Heller myotomy.

OPERATIVE PLANNING

The patient is placed under general anesthesia and intubated with a double-lumen endotracheal tube so that the left lung can be deflated during the procedure. As for a left thoracotomy, the patient is placed in the right lateral decubitus position over an inflated bean bag. The instrumentation is similar to that for a laparoscopic Nissen or Guarnier fundoplication. Instead of conventional trocars, four or five thoracoports with blunt obturators are employed, because insufflation of the thoracic cavity is not required. The myotomy can be performed with a monopolar hook cautery, bipolar scissors, or an ultrasonic scalpel. A 30° scope and a 45° scope are essential for thoracoscopic procedures. In addition, an endoscope is used for intraoperative endoscopy.

OPERATIVE TECHNIQUE

Step 1: Placement of Thoracoports

Five ports are usually placed [see *Figure 11*]. Port A, used for the 30° scope, is inserted in the sixth intercostal space about 3.5 to 5 cm behind the posterior axillary line. Port B, used for the lung retractor, is placed in the third intercostal space about 1.25 to 2.5 cm anterior to the posterior axillary line. Port C, used for insertion of a grasper, is placed in the sixth intercostal space in the anterior axillary line. Port D, used for insertion of the instrument employed for the myotomy, is placed in the seventh intercostal space in the midaxillary line. Port E is placed in the eighth intercostal space between the anterior axillary line and the midaxillary line. This port is optional: it is needed in about 30% of cases to allow the surgeon to obtain further exposure of the esophagogastric junction through retraction of the diaphragm.

Troubleshooting A common mistake is to insert port A too anteriorly. This port must be placed well beyond the

Figure 11 Left thoracoscopic myotomy. Illustrated is the recommended placement of the thoracoports.

posterior axillary line to provide the best angle for the 30° scope. Often, the other ports are placed one or two intercostal spaces too high. This mistake hampers the performance of the most delicate portion of the operation, the myotomy of the distal portion of the esophagus and the stomach.

Sometimes, chest wall bleeding occurs as a consequence of port insertion. This bleeding will obscure the operating field and therefore must be stopped before the intrathoracic portion of the procedure is begun. This is accomplished either by using the cautery from the inside or by applying a stitch from the outside if an intercostal vessel has been damaged.

Step 2: Retraction of Left Lung and Division of Inferior Pulmonary Ligament

Once the ports are in place, the deflated left lung is retracted cephalad with a fan retractor introduced through port B. This maneuver places tension on the inferior pulmonary ligament, which is then divided. After the ligament is divided, the fan retractor can be held in place by a self-retaining system fixed to the operating table.

Troubleshooting Before the inferior pulmonary ligament is divided, the inferior pulmonary vein must be identified to prevent a life-threatening injury to this vessel. If oxygen saturation decreases, particularly in patients with lung disease, the retractor should be removed and the lung inflated intermittently.

Step 3: Division of Mediastinal Pleura and Dissection of Periesophageal Tissues

The mediastinal pleura is divided, and the tissues overlying the esophageal wall are dissected until the wall of the esophagus is visible. This maneuver varies in difficulty depending on the width of the space between the aorta and the pericardium (which sometimes is very small) and on the size and shape of the esophagus. Large (sigmoid) esophagi tend to curve to the right, which makes identification of the wall difficult. If the esophagus is not immediately apparent, it can be easily identified in the groove between the heart and the aorta by means of transillumination provided by an endoscope [see Figure 12].

Figure 12 Left thoracoscopic myotomy. The esophagus may be identified by means of transillumination from the endoscope.

Troubleshooting The endoscope placed inside the esophagus at the beginning of the procedure plays an important role. In the early stages of the procedure, it allows identification of the esophagus via transillumination. When the light intensity of the 30° scope is turned down, the esophagus appears as a bright structure. In addition, tilting the tip of the endoscope brings the esophagus into view as it is lifted from the groove between the aorta and the heart.

Step 4: Initiation of Myotomy and Entry into Submucosal Plane at Single Point

As in a laparoscopic Heller myotomy, it is helpful to mark the surface of the esophagus along the line through which the myotomy will be carried out. The myotomy is started halfway between the diaphragm and the inferior pulmonary vein. Again, the proper submucosal plane should be reached at a single point before the myotomy is extended upward and downward.

Troubleshooting Troubleshooting for this step is essentially the same as that for step 8 of a laparoscopic Heller myotomy, with the exception that here the myotomy is started 4 to 5 cm (rather than 3 cm) above the esophagogastric junction.

Step 5: Proximal and Distal Extension of Myotomy

Once the mucosa has been exposed, the myotomy can safely be extended proximally and distally [see Figure 13]. We usually extend the myotomy for about 5 mm onto the gastric wall, without adding an antireflux procedure.^{3,4} Typically, the total length of the myotomy is about 6 cm for patients with achalasia.

Troubleshooting Proximally, the myotomy is extended all the way to the inferior pulmonary vein only in cases of vigorous achalasia (high-amplitude simultaneous contractions associated with chest pain in addition to dysphagia) or diffuse

Figure 13 Left thoracoscopic myotomy. Shown are the distal and proximal extensions of the myotomy.

esophageal spasm; otherwise, it is limited to the distal 5 to 6 cm of the esophagus. If a longer myotomy is needed, the lung is displaced anteriorly and the myotomy extended to the aortic arch.

Distally, the myotomy is continued for 5 mm past the esophagogastric junction. The endoluminal view provided by the endoscope is useful for assessing the location of the esophagogastric junction. Often, the stomach is distended by the air insufflated by the endoscope and pushes the diaphragm upward, thereby limiting the view of the esophagogastric junction. If sucking air out of the stomach does not resolve this problem, an additional port (i.e., port E) may be placed in the eighth intercostal space, and a fan retractor may be introduced through this port to push the diaphragm down.

Because the myotomy of the gastric wall is the most challenging part of the operation, good exposure is essential. It is at this level that an esophageal perforation is most likely to occur. The risk is particularly high in patients who have undergone pneumatic dilatation or injection of botulinum toxin, both of which may lead to the replacement of muscle layers by scar tissue and the consequent loss of the regular planes. Perforations recognized in the operating room can be repaired by thoracoscopic intracorporeal suturing or, if this fails, by thoracotomy and open repair. The gastric fundus can be used to buttress the repair. If it is unclear whether a perforation has occurred, the esophagus should be covered with water and air insufflated through the endoscope; bubbling will be observed over the site of any perforation present.

Step 6: Insertion of Chest Tube and Removal of Thoracoports

A 24 French angled chest tube is inserted under direct vision through port D or port E. The ports are removed under direct vision, and the thoracic wall is inspected for bleeding.

COMPLICATIONS

As with laparoscopic Heller myotomy, delayed esophageal leakage is a common postoperative complication, and treatment options are similar.

If the myotomy is not extended far enough onto the gastric wall, residual dysphagia occurs. To prevent this problem, the distal extent of the myotomy should be assessed by means of endoscopy with the goal of including 5 mm of the gastric wall. Patients with residual dysphagia must be evaluated by means of esophageal manometry, which will document the extent of the residual high-pressure zone and the pressure within it. The myotomy can be easily extended by a laparoscopic approach, and a Dor fundoplication can be added.

If, on the other hand, the myotomy is extended too far onto the gastric wall, abnormal gastroesophageal reflux occurs. Some patients present with heartburn; others are asymptomatic. It is essential to evaluate patients postoperatively with manometry and prolonged pH monitoring. Mild reflux can be treated with acid-reducing medications, particularly in elderly patients. In younger patients, abnormal reflux should be corrected with a laparoscopic partial fundoplication (e.g., Dor fundoplication).

POSTOPERATIVE CARE

Patients are started on a liquid diet the morning of postoperative day 1; on postoperative day 2, they are started on a soft mechanical diet, which is continued for the rest of the first week. We do not routinely obtain an esophagogram before starting feedings. The chest tube is removed after 24 hours if the lung is fully expanded and there is no air leak. Patients are discharged after 48 to 72 hours and are able to resume regular activities in 7 to 10 days.

OUTCOME EVALUATION

The results obtained with thoracoscopic myotomy are generally comparable to those obtained with corresponding open surgical procedures. In a 1999 study from UCSF, 26 (87%) of the first 30 patients with achalasia who were treated in this fashion experienced good or excellent results [see Table 2].³ At present, however, this procedure is rarely used to treat esophageal achalasia: laparoscopic Heller myotomy and Dor fundoplication is now the treatment of choice.⁴⁵

Reoperation for GERD

Currently, an increasing number of patients are being seen for evaluation and treatment of foregut symptoms after laparoscopic antireflux surgery. These patients are treated as follows.

PREOPERATIVE EVALUATION

Some degree of dysphagia, bloating, and abdominal discomfort is common during the first 6 to 8 weeks after a fundoplication. If these symptoms persist or heartburn and regurgitation occur, a thorough evaluation (with barium swallow, endoscopy, esophageal manometry, and pH monitoring) is carried out with the aim of answering the following three questions:

1. Are the symptoms attributable to persistent gastroesophageal reflux?
2. Are the symptoms attributable to the fundoplication itself?
3. Can the cause of the failure of the first operation be identified and corrected by a second operation?

Many patients report heartburn after a fundoplication. It is often assumed that this symptom must be the result of a failed operation and that acid-reducing medications should be restarted. In most cases, however, this assumption is mistaken:

Table 2 Results of Thoracoscopic Myotomy in 30 Patients with Achalasia³

Results	Patients (% of Total)
Excellent (no dysphagia)	21 (70)
Good (dysphagia < once/wk)	5 (17)
Fair (dysphagia > once/wk)	3 (10)
Poor (persistent dysphagia)	1 (3)

postoperative pH monitoring yields abnormal results in only about 20% of patients.⁴⁶ The value of manometry lies in its ability to document the changes caused by the operation at the level of the LES and the esophageal body. The pH monitoring assesses the reflux status and determines whether there is a correlation between symptoms and actual episodes of reflux. If abnormal reflux is in fact present, the therapeutic choice is between medical therapy and a second operation.

Other patients complain of dysphagia arising *de novo* after the operation. This symptom is usually attributable to the operation itself and may occur in the absence of abnormal reflux. In addition to manometry and pH monitoring, a barium swallow is essential to define the anatomy of the esophagogastric junction. A study from the University of Washington found that the anatomic configurations observed could be divided into three main types: (1) type I hernia, in which the esophagogastric junction was above the diaphragm (subdivided into type IA, with both the esophagogastric junction and the wrap above the diaphragm, and type IB, with only the esophagogastric junction above the diaphragm); (2) type II hernia, a paraesophageal configuration; and (3) type III hernia, in which the esophagogastric junction was below the diaphragm and there was no evidence of hernia but in which the body of the stomach rather than the fundus was used for the wrap.⁴⁷ In 10% of patients, however, the cause of the failure could not be identified preoperatively.³⁸

Some patients present with a mix of postprandial bloating, nausea, and diarrhea. These symptoms may be the result of damage to the vagus nerves. Radionuclide evaluation of gastric emptying often helps quantify the problem.

OPERATIVE PLANNING

Patient preparation (i.e., anesthesia, positioning, and instrumentation) for a reoperation for reflux is identical to that for the initial laparoscopic fundoplication.

OPERATIVE TECHNIQUE

We do not routinely attempt a second antireflux operation laparoscopically. To provide a stepwise technical description that would be suitable for all reoperations for reflux is impossible, because the optimal procedure depends on the original approach (open versus laparoscopic), the severity of the adhesions, and the specific technique used for the first operation (total or partial fundoplication). The key goals of reoperation for reflux are as follows.

1. To dissect the wrap and the esophagus away from the crura. This is the most difficult part of the operation. The major complications seen during this part of the procedure are damage to the vagus nerves and perforation of the esophagus and the gastric fundus.
2. To take down the previous repair. The earlier repair must be completely undone and the gastric fundus returned to its natural position. If the short gastric vessels were not taken down during the first procedure, they must be taken down during the second.
3. To dissect the esophagus in the posterior mediastinum so as to have enough esophageal length below the diaphragm and avoid placing tension on the repair.
4. To reconstruct the cardia. The same steps are followed as for a first-time repair. If, after extensive esophageal mobilization, the esophagogastric junction remains above

the diaphragm (short esophagus), esophageal lengthening can be accomplished by adding a thoracoscopic Collis gastroplasty to the fundoplication. To date, however, we have never found this step to be necessary.

COMPLICATIONS

Because the risk of gastric or esophageal perforation or damage to the vagus nerves is much higher during a second antireflux operation, the surgeon must proceed with extreme care, making sure to identify structures completely before dividing them. Most perforations are recognized and repaired intraoperatively. Leaks manifest themselves during the first 48 hours. Peritoneal signs are noted if the spillage is limited to the abdomen; shortness of breath and a pleural effusion are noted if spillage also occurs in the chest. The site of the leak should always be confirmed by means of a contrast study with barium or a water-soluble agent. Perforation is best handled with laparotomy and direct repair of the leak.

OUTCOME EVALUATION

Whereas the success rate is around 80 to 90% for a first antireflux operation, it falls to 70 to 80% for a second such operation. In our view, a second operation should be attempted by an expert team only if medical management fails to control heartburn or dilatation has not relieved dysphagia.

Reoperation for Esophageal Achalasia

Laparoscopic Heller myotomy improves swallowing in more than 90% of patients. What causes the relatively few failures reported is still incompletely understood. Typically, a failed Heller myotomy is signaled either by persistent dysphagia or by recurrent dysphagia that develops after a variable symptom-free interval following the original operation.

A complete workup (routinely including barium swallow, endoscopy, manometry, and pH monitoring) is required before treatment is planned. In addition, it is our practice to review the video of the first operation to search for technical errors that might have been responsible for the poor outcome. Such errors typically fall into one of the following three categories.

1. A myotomy that is too short either distally or proximally. If the myotomy is too short distally, a barium swallow shows persistent distal esophageal narrowing and manometry shows a residual high-pressure zone. If the myotomy is too short proximally, it will be apparent from the barium swallow.
2. A constricting Dor fundoplication. Often, manometry and pH monitoring yield normal results, but a barium swallow shows slow passage of contrast media from the esophagus into the stomach. In one study from UCSF,⁴⁰ problems with Dor funduplications occurred in four (4%) of 102 patients. Analysis of the video records of the first operations showed that in three of the four patients, all the stitches in the right suture row had incorporated the esophagus, the right pillar of the crus, and the stomach, thereby constricting the myotomy. In one patient, the short gastric vessels had not been taken down, and the body of the stomach rather than the fundus had been used for the fundoplication.
3. Transmural scarring caused by previous treatment. In patients treated with intrasphincteric injection of botulinum toxin, transmural fibrosis can sometimes be found at the level of the esophagogastric junction. This

unwelcome finding makes the myotomy more difficult and the results less reliable.

There are two treatment options for persistent or recurrent dysphagia after Heller myotomy: (1) pneumatic dilatation and (2) a second operation tailored to the results of preoperative evaluation. In a 2002 study,⁴⁸ pneumatic dilatation was successfully used to treat seven of 10 patients who experienced dysphagia postoperatively; of the remaining three patients, two required a second operation and one refused any treatment.

Reoperation for achalasia is technically challenging. It is of paramount importance to avoid perforating the exposed

esophageal mucosa during the dissection. A small hole can be repaired, but a larger laceration might necessitate an esophagectomy. This option should always be discussed with the patient before the operation. It is our belief that the surgeon attempting a reoperation after a failed attempt at surgical treatment of achalasia should perform a laparotomy, even though several reports have stressed the feasibility of laparoscopic reoperation after a failed myotomy.⁴⁹

Overall, about 10 to 20% of patients experience some degree of dysphagia after a Heller myotomy. Pneumatic dilatation, a second myotomy, or both should always be tried before an esophagectomy is considered.

9 CHEST WALL PROCEDURES

Bryon J. Boulton, MD, and Seth D. Force, MD

Chest wall procedures are an important component of any thoracic surgeon's practice. The approach to these procedures is somewhat different from the approach to esophageal or pulmonary resections and requires specific knowledge of thoracic musculoskeletal anatomy, as well as of the different types of autologous and artificial grafts available for chest wall reconstruction. Broadly, chest wall procedures may be divided into those performed to treat congenital chest wall disease and those done to treat acquired disease. In what follows, we describe the major surgical techniques in both categories and review the pitfalls that may accompany them.

Procedures for Congenital Chest Wall Disease

Congenital chest wall defects arise from abnormal development of the sternum, the costal cartilages, and the ribs. Such defects include pectus excavatum (funnel chest), pectus carinatum (pigeon chest), cleft sternum, and Poland syndrome (absence of the breast and the underlying pectoralis muscle and ribs). Of these, pectus excavatum is by far the most common, accounting for more than 90% of all congenital chest wall procedures; accordingly, the ensuing discussion focuses on the surgical aspects of pectus excavatum repair.

REPAIR OF PECTUS EXCAVATUM

Preoperative Evaluation

Because pectus excavatum occurs in varying degrees of severity, patients may seek surgical treatment for any of a number of different reasons, such as shortness of breath, early fatigue with exercise, or simple dissatisfaction with their appearance. Thus, one of the most important tasks for surgeons treating pectus excavatum is determining which patients are candidates for operative management. In an attempt to facilitate this determination, the Congenital Heart Surgery Nomenclature and Database Project has developed a classification system for pectus excavatum, in which a deformity less than 2 cm in depth is classified as mild, a deformity 2 to 3 cm in depth is classified as moderate, and a deformity greater than 3 cm in depth is classified as severe.¹ A computed tomography (CT)-based index has also been devised, in which the transverse chest diameter is divided by the anteroposterior diameter; an index greater than 3.2 is considered indicative of severe disease.²

These classification attempts notwithstanding, the precise indications for surgery remain unclear. Many studies have attempted to show that the depressed sternum leads to pulmonary compromise, but, for the most part, these studies have had small sample sizes and have employed differing measures of lung function, both of which have made accurate comparisons difficult. In one study that included 25 US Air Force personnel with symptomatic pectus excavatum, lung volumes were comparable to those in normal persons, but

there was a significant difference in maximum voluntary ventilation.³ In a study that compared 37 patients who had undergone surgical repair of pectus excavatum both with normal persons and with persons who had uncorrected deformities, no differences in physical working capacity among the three groups were noted.⁴ Other studies have reported improvements in exercise tolerance and regional ventilation and perfusion after surgical repair of pectus excavatum.^{5,6} On the other hand, some investigators have reported decreases in pulmonary function in symptomatic patients after corrective surgery. One group attributed this result to overly aggressive resection in very young patients that led to growth restriction of the chest wall; accordingly, they recommended delaying surgical repair until 6 to 8 years of age.⁷

Severe pectus excavatum has also been reported to cause cardiac dysfunction secondary to sternal compression of the right ventricle. Several early studies found stroke volume and cardiac output to be lower in exercising upright patients than in supine patients.^{8,9} However, improvement in cardiac function after pectus excavatum repair has not been universally documented. In one study, first-pass radionuclide angiocardiology failed to show any improvements in left ventricular function after repair of pectus excavatum.¹⁰ At present, there is no consensus on the cardiopulmonary benefits of pectus excavatum repair, and the major reasons for surgical treatment are still patient discomfort and dissatisfaction with appearance.

Operative Technique

A number of different procedures have been employed to treat pectus excavatum, but, for present purposes, we focus on (1) the Ravitch procedure (and variations thereof) and (2) the Nuss procedure. For historical reasons, the turnover technique, originally described by Judet and Judet¹¹ and later employed by Wada and colleagues,¹² warrants a brief mention. Wada and colleagues' series included 199 patients whose deformities were corrected with a version of this technique; good results were achieved in 63% of patients, and there were only three instances of partial sternal necrosis. Today, however, the turnover technique is rarely used because of the good results that can be achieved with techniques that do not carry a risk of sternal necrosis. It is usually reserved for extreme cases of pectus excavatum, which often include deformities of the sternum in addition to abnormalities of the costal cartilages.

Ravitch procedure Repair of pectus excavatum is based on the principle that the deformity is secondary to abnormal growth of the costal cartilages. Accordingly, correction involves (1) resection of the abnormal cartilages, (2) a transverse anterior sternal osteotomy to allow anterior displacement of the sternum, and (3) sternal fixation to

prevent posterior displacement after the repair. Most of the variations in the Ravitch procedure have to do with the use of different sternal fixation techniques.

Step 1: initial incision and exposure Either a midline incision or a bilateral inframammary incision is made [see Figure 1a, b]; the latter incision yields superior cosmetic results, especially in female patients, but necessitates the elevation of large subcutaneous skin flaps to the level of the angle of Louis or the sternal notch superiorly and to the xiphoid process inferiorly. The pectoralis muscles are then mobilized from the chest wall, beginning medially and proceeding laterally until the costal cartilages are exposed [see Figure 1c].

Step 2: resection of abnormal cartilages For each abnormal costal cartilage, the anterior perichondrium is scored with the electrocautery along the length of the cartilage, and the cartilage is dissected from the perichondrium with a periosteal elevator [see Figure 2a]. The posterior plane between the cartilage and the perichondrium is then developed in one area, and the cartilage is divided with a scalpel between the jaws of a right-angle clamp [see Figure 2b]. The cut end of the cartilage is grasped with a clamp, and the rest of the cartilage is dissected from the perichondrium. Once the correct plane is established, the dissection can be facilitated by gently pushing the perichondrium off the cartilage with a finger. The entire cartilage should be removed from the sternum to the rib, with every attempt made to maintain the integrity of the perichondrium. During this part of the procedure, the xiphoid process is also detached from the sternum. The

extent of cartilage removal depends on the individual defect present but usually includes the third rib.

Step 3: sternal osteotomy An osteotomy is made in the upper anterior table of the sternum with either a periosteal elevator or a small reticulating bone saw [see Figure 3a], and the posterior table of the sternum is fractured. The sternum can then be angled anteriorly. When the desired angle is reached, the osteotomy is closed with three interrupted nonabsorbable sutures or with microplates and screws [see Figure 3b, c]. At this point, rotational sternal defects can be corrected by making anterior and posterior lateral osteotomies on either side of the sternum and then closing the osteotomies with sutures or microplates.

Step 4: sternal fixation Sternal fixation can be accomplished by any of several means. Posterior sternal support can be achieved by placing a Kirschner wire or retrosternal bar that is secured to the periosteum of the rib and left in place for approximately 3 months after operation [see Figure 4]. Alternatively, the sternum can be supported with a piece of polypropylene mesh or with two polypropylene sutures sutured to the xiphoid process and then brought around the right and left second ribs.¹³

Step 5: closure and drainage The pectoralis muscles are reapproximated in the midline, closed suction drains are placed in the subcutaneous flaps, and the subcutaneous layer and the skin are closed. To prevent seroma formation, one closed suction drain may be placed posterior to the pectoralis muscles and another between the pectoralis muscles and the subcutaneous layer; the right pleural space may then be

Figure 1 Repair of pectus excavatum: Ravitch procedure. The procedure begins with a midline incision (a) or a bilateral inframammary incision (b). The pectoralis muscles are then dissected off the chest wall (c).

Figure 2 Repair of pectus excavatum: Ravitch procedure. (a) The anterior perichondrium is opened, and the abnormal cartilage is dissected free with a periosteal elevator. (b) The cartilage is divided.

Figure 3 Repair of pectus excavatum: Ravitch procedure. (a) An osteotomy is made in the upper sternum. (b) The sternum is angled anteriorly; when the desired angle is reached, the osteotomy is closed. (c) Shown is a lateral view of the sternal angle before and after correction.

opened anteriorly and a right pleural tube placed through a separate incision.¹⁴

Nuss procedure Minimally invasive repair of pectus excavatum, also referred to as the Nuss procedure, has gained popularity over the past decade.

Step 1: configuration of bar The patient is placed in the supine position with the arms abducted, and marks are made on either side of the chest at spots that correspond to the deepest point of the defect. The bar that will be used for the repair is shortened to a length equivalent to the measured distance between the two midaxillary lines minus 1 cm. A complex series of bends are then placed in the bar to match its contours to those of the patient's deformity.

Step 2: initial incisions and creation of intrathoracic tunnel Incisions are made in the right and left midaxillary lines at the level of the marks, and a subcutaneous flap is raised from each incision and extended to the defect. A Crawford vascular clamp or a Lorenz pectus introducer is then placed through the right intercostal space under thoracoscopic visualization and advanced along the posterior sternum and out the corresponding left intercostal space [see Figure 5].

Step 3: placement and fixation of bar An umbilical tape is pulled through the anterior mediastinum and attached to the bar, which is then gently pulled, with the concave side up, through the intercostal space. A Lorenz pectus bar rotator is employed to flip the bar over, and the ends of the bar are positioned in the subcutaneous space [see Figure 6]. Occasionally, for proper alignment, the bar may have to be removed and rebent, or stabilizers may have to be placed alongside it.

Figure 5 Repair of pectus excavatum: Nuss procedure. Incisions are made on either side of the chest. A Crawford vascular clamp is inserted through the right intercostal space and advanced along the sternum and out the left intercostal space.

When the bar is correctly positioned, it is sutured to the chest wall musculature with an absorbable suture on one end and a permanent suture on the other.

The bar is usually left in place for 2 years. Excellent results have been reported.¹⁵ Significant complications include bar displacement necessitating reoperation (9.2% of procedures), pneumothorax (4.8%), infection (2%), and pleural effusion (2%). Rare complications include cardiac injury, thoracic outlet syndrome (TOS), pericarditis, and sternal erosion caused by the bar.

Outcome Evaluation

In general, the results of pectus excavatum repair are good, and the overall complication rate is low. In one study, 90% of 76 patients operated on over a 30-year period experienced excellent outcomes, and only one patient required reoperation for a recurrent defect.¹⁴ The incidence of complications (pleural effusions, pneumonia, and wound seromas) was 14%.¹⁴ In another study, no operative deaths occurred in more than 800 repairs, and only a few cases of serious infections and bleeding were reported.¹⁶ Other investigators have reported rare complications arising from the migration of sternal support bars and wires.¹⁷

REPAIR OF PECTUS CARINATUM

Operative Technique

Surgical repair of pectus carinatum resembles surgical repair of pectus excavatum in several respects. The same skin incision is employed, and the pectoralis major muscles are elevated in a similar manner. Subperichondrial resection of the abnormal cartilages is then carried out, usually extending to the second costal cartilage. Next, a generous V-shaped osteotomy is made in the upper portion of the sternum at the point of maximal protrusion, which is usually near the insertion of the second cartilage. Occasionally, a second osteotomy is required near the caudal end of the sternum to facilitate elevation of the manubrium and depression of the sternum.

Figure 6 Repair of pectus excavatum: Nuss procedure. (a) The pectus bar is pulled into the tunnel opened by the vascular retractor and then flipped to provide the desired chest contour. (b) The ends of the bar are then sutured to the chest wall musculature.

Finally, the osteotomy is closed with nonabsorbable monofilament sutures, drains are placed, and soft tissue is closed as in a pectus excavatum repair.

Outcome Evaluation

The results of pectus carinatum repair are generally comparable to those of pectus excavatum repair. Most patients experience good outcomes, and operative morbidity is low.

Procedures for Acquired Chest Wall Disease

TRANSAXILLARY FIRST RIB RESECTION FOR THORACIC OUTLET SYNDROME

Preoperative Evaluation

TOS results from compression of the subclavian blood vessels or the brachial plexus as these structures exit the bony thorax. Symptoms may be primarily vascular (e.g., arm swelling or loss of pulse) or neurogenic (e.g., pain and paresthesias). The workup for TOS includes a detailed physical examination, as well as imaging and nerve conduction studies.

Operative Planning

Surgical treatment of TOS typically involves resection of the first rib, which widens the thoracic outlet and relieves the neurovascular impingement. First rib resection can be accomplished via several different approaches, including posterior, supraclavicular, infraclavicular, transthoracic, and transaxillary. I focus here on the transaxillary approach, which provides good exposure of the first rib and allows the surgeon to avoid the subclavian blood vessels and the brachial plexus. Regardless of the specific surgical approach followed, any surgeon embarking on a first rib resection must have a detailed knowledge of the thoracic outlet to keep from injuring the neurovascular structures in the area.

Operative Technique

The patient is placed in the lateral decubitus position, and the affected arm is kept at a 90° angle either by an arm holder or, alternatively, by an assistant. Care must be taken not to hyperabduct or hyperextend the shoulder. The arm, the

axilla, and the chest are prepared and draped into the sterile field.

Step 1: initial incision and exposure An incision is made just below the axillary hair line and extended from the pectoralis major to the latissimus dorsi [see Figure 7]. The subcutaneous tissue is incised down to the chest wall with the electrocautery, with care taken to stay perpendicular to the axis of the chest. Dissection is then begun along the chest wall and carried toward the first rib. The intercostal brachial

Figure 7 Transaxillary first rib resection. Shown are the transaxillary incision and the thoracic outlet anatomy.

nerve is identified where it exits between the first and second ribs. This nerve should be spared: dividing it leads to numbness of the upper inner biceps region.

Step 2: dissection and division of anterior portion of first rib When the first rib is encountered, it is dissected from the periosteum with a periosteal elevator. Dissection is continued anteriorly along the rib until just past the subclavian vein, at which point a right-angle clamp can be passed around the rib in the subperiosteal plane. A Gigli saw or a first rib cutter is then used to divide the anterior portion of the rib [see Figure 8a].

Next, the first rib is retracted inferiorly to permit visualization of the anterior scalene muscle, which is then divided at its attachment to the rib. To prevent thermal injury to the phrenic nerve, a scalpel rather than an electrocautery is used to divide the muscle [see Figure 8b]. Care should also be taken not to injure the subclavian vein and artery, which lie anterior and posterior to the anterior scalene muscle, respectively. As an alternative, the anterior scalene muscle may be divided before the anterior portion of the rib is cut.

Step 3: dissection and division of posterior portion of first rib The subperiosteal dissection is continued posteriorly, freeing the first rib from the pleura, the subclavian vessels, and the brachial plexus. The posterior portion of the rib is then divided with a first rib cutter as close as possible to the articulation of the rib with the transverse process. Every effort should be made to keep from injuring the C8 and T1 nerve roots.

Step 4: closure The incision is closed without drainage. If the pleura was inadvertently entered, air may be aspirated from the chest with a red rubber tube, which is removed before the subcutaneous tissue is closed. One authority recommends further neurolysis of the C7 to T1 nerve roots and the middle and lower trunks of the brachial plexus, as well as resection of the anterior and middle scalene muscles up into the neck.¹⁸

Complications

Surgical complications include injuries to the subclavian vein and artery (leading to massive blood loss), the brachial plexus, the phrenic nerve, the long thoracic nerve, and the thoracic duct.

Outcome Evaluation

The long-term results of first rib resection appear to be independent of the exposure technique employed. Good results, defined as relief of major symptoms, have been reported in as many of 90% of patients in the first year and in as many as 70% of patients 5 to 10 years after operation. Considerable debate continues over the preferred surgical approach, but, to date, no studies have shown any one approach to have significant advantages over any of the others.

CHEST WALL RESECTION

Chest wall resection has become a critical component of the thoracic surgeon's armamentarium. It may be performed to treat either benign conditions (e.g., osteoradionecrosis, osteomyelitis, and benign neoplasms) or malignant disease.

Figure 8 Transaxillary first rib resection. (a) The anterior portion of the first rib is cut. (b) The anterior scalene muscle is then divided.

Preoperative Evaluation

Preoperative imaging studies may include chest x-ray, chest CT [see Figure 9], and magnetic resonance imaging if vertebral involvement is suspected. The other preoperative tests ordered are much the same as those required for any other large thoracic procedure, including pulmonary function testing, nutritional assessment, and cardiac stress testing in patients who are older or have a history of cardiac disease.

Operative Planning

Operative planning for chest wall resection should include establishing the extent of the resection, weighing options for chest wall stabilization, and deciding on the method of tissue coverage to be employed. A multidisciplinary approach, involving the participation of a neurosurgeon and a plastic surgeon, may be required.

The technique of chest wall resection is essentially the same for benign conditions as for malignant ones and is mainly dependent on the location of the lesion. For malignant tumors of the chest wall, a 5 cm margin, or at least resection of one uninvolved rib above and below the tumor, is required. Additionally, any involved skin and any biopsy site must be resected along with the chest wall specimen. For infection or osteoradionecrosis, the resection must include all nonviable skin and underlying bone; if it does not, skin and muscle flaps may not heal properly. Any destroyed lung tissue may also have to be resected along with the chest wall specimen. In addition, recurrent cancer must be ruled out before the operation can proceed. A particular challenge is posed by breast cancer patients who have already had muscle flaps for breast reconstruction; in these patients, tissues other than muscle (e.g., omentum) may be required for tissue coverage after chest wall resection.

Standard Chest Wall Resection

In cases in which a concomitant lung resection is required, the chest wall resection is usually performed first; this measure renders the lung more mobile and facilitates the pulmonary resection. The lateral decubitus position is the best choice for most combined lung–chest wall procedures, whereas the supine position is preferable for isolated anterior chest wall procedures. If a larger chest wall resection is

Figure 9 Chest computed tomographic scan reveals a large pulmonary and chest wall mass.

expected, every attempt should be made to spare major muscle groups so that these muscles can be used later to cover any prosthetic material used in reconstruction.

Operative technique

Step 1: initial incision and exposure The usual incision is a standard posterolateral thoracotomy incision through the fifth interspace.

Step 2: determination of extent of required chest wall resection As soon as the pleura is opened, the surgeon should palpate the tumor to evaluate the extent of chest wall involvement, which determines the extent of the resection. Removal of uninvolved ribs may make reconstruction of the chest wall more complicated. For example, posterior resections that do not require removal of the fifth rib are protected by the scapula, so reconstruction is unnecessary. If the fifth rib is removed, however, the tip of the scapula will tend to become stuck under the sixth rib with shoulder movement; this is very uncomfortable for the patient, and chest wall reconstruction will therefore be required at the time of resection.

At this point, the surgeon should also rule out diffuse pleural disease before proceeding with resection. In some cases, the tumor can be removed by means of extrapleural dissection, without any need for chest wall resection. If there is any suspicion of chest wall involvement, however, chest wall resection is mandatory because leaving any tumor behind guarantees a recurrence.

The extent of the chest wall resection is marked with the electrocautery on the outside of the thoracic cavity. At least one grossly uninvolved rib should be included both above and below the tumor.

Step 3: completion of anterior boundary of resection Initially, the periosteum over the lowest rib to be resected is scored, and a periosteal elevator is used to separate the intercostal bundle from the rib. Alternatively, the intercostal bundle can be doubly ligated and divided at the anterior resection margin. Once the intercostal vessels are cleared from the lowest rib, the electrocautery is used to divide the pleura below the rib toward the anterior boundary of the resection. The rib is then divided with a rib cutter, with care taken to ensure a margin of at least 5 cm from the tumor [see Figure 10]. Next, the intercostal bundle of the next higher rib is ligated and divided, the intercostal muscle is divided with the electrocautery, and the rib is cut with a rib cutter in the same manner as the previous rib. This process is repeated until the anterior boundary of resection is completed. A subperiosteal plane is then developed over the highest rib to be resected, the adjacent intercostal bundle is separated from the rib, and the parietal pleura is divided with the electrocautery.

Step 4: completion of posterior boundary of resection If the tumor margin does not involve the vertebrae, the posterior portion of the chest wall resection is identical to the anterior portion [see Step 3, above]. If, however, the tumor appears to encroach on the head of the rib or the transverse process, it will be necessary to disarticulate the rib from the transverse process or, in the latter situation, remove the transverse process entirely.

Figure 10 Chest wall resection. The anterior and posterior margins of the required resection are determined. The anterior margin is completed first.

Disarticulation of the rib from the transverse process is performed by dissecting the paraspinal ligament and erector spinae muscles away from the spine with the electrocautery, thereby exposing the joint between the head of the rib and the transverse process. The ligaments attaching the rib to the transverse process are then incised with the electrocautery, and an osteotome is inserted into the joint, which is then levered anteriorly and posteriorly to disarticulate the rib from the transverse process [see Figure 11]. The intercostal neurovascular bundle must be ligated and divided at this point:

Figure 11 Chest wall resection. Depicted is disarticulation of the rib from the transverse process.

failure to do so will result in bleeding and possibly in leakage of cerebrospinal fluid (CSF). If bleeding occurs, it can be controlled with bipolar electrocauterization and temporary packing with a hemostatic agent. The hemostatic agent must not be left in place permanently, because it may expand or result in a neural foramen hematoma, and either of these events can lead to spinal cord compression and significant neurologic injury. If at any time the surgeon feels uncomfortable about ongoing intercostal bleeding or a possible CSF leak, intraoperative neurosurgical consultation should be obtained. In cases in which the tumor involves the transverse process, this structure must be removed from the vertebral body with an osteotome and a mallet or with a first rib cutter. If the tumor has invaded the vertebral body and resection is still being considered, neurosurgical consultation should be obtained. Generally, if the tumor involves more than one quarter of the vertebral body or extends into multiple vertebral levels, it is considered unresectable.

Step 5: lung resection (if required) Once the posterior chest wall margin has been completed, the lung resection (if required) is performed. The entire lung–chest wall specimen is then submitted for pathologic examination, and histopathologic margins are obtained both on the lung and on the chest wall. If the chest wall margins are positive, the involved area must be trimmed back and a new margin submitted.

Step 6: chest wall reconstruction Chest wall reconstruction is required for all anterior defects and for posterior defects that involve any rib lower than the fourth rib. Reconstruction can be performed either with polypropylene or Gore-Tex (W. L. Gore and Associates, Flagstaff, Arizona) mesh or with a polypropylene-methylmethacrylate sandwich. The latter is employed when rigid reconstruction is warranted (as in anterior reconstruction); it not only provides added protection of pleural and mediastinal structures but also creates a better cosmetic effect by recreating the shape of the chest wall.

To create the polypropylene-methylmethacrylate sandwich, two pieces of polypropylene mesh are cut to the size of the defect. A thin layer of methylmethacrylate cement is spread on one of the mesh pieces, and the other piece is then applied over the methylmethacrylate layer. As this sandwich begins to harden, it is molded to the contours of the chest wall, with care taken to protect the patient's skin against injury from the heat given off by the hardening cement. When the sandwich is sufficiently hardened, it is sewn to the ribs with 0 polypropylene sutures [see Figure 12a]. The sutures may be passed around the uppermost and lowermost ribs and may be placed directly through the anterior and posterior margins [see Figure 12b]. If rib disarticulation was required to complete the posterior margin, holes may be drilled in the transverse processes and the sutures passed through these holes; alternatively, the sandwich may be sutured to the paraspinal ligament.

If polypropylene or Gore-Tex mesh is used without cement, it should be cut to a size smaller than that of the defect. Thus, the mesh will effectively be stretched when it is sutured to the chest wall, and any laxity in the reconstruction will thereby be alleviated.

Step 7: closure and drainage The serratus anterior and the latissimus dorsi are closed in the standard fashion, as

Figure 12 Chest wall resection. (a) A polypropylene-methylmethacrylate sandwich is created by spreading a layer of methylmethacrylate cement between two pieces of polypropylene mesh. When sufficiently hardened, the sandwich is sutured to the ribs. (b) Photograph shows a polypropylene-methylmethacrylate sandwich sutured in place.

are the subcutaneous and skin layers. With the exception of pleural tubes, drains are not routinely used. Special attention should be paid to postoperative analgesia: patients who have undergone extensive resections often experience considerable pain and are therefore prone to atelectasis and pneumonia. Epidural analgesia should be employed routinely in such cases.

Troubleshooting If chest wall infection is a possibility (as with osteoradionecrosis or osteomyelitis), alternative reconstructive techniques are required to obviate concerns about superinfection resulting from the use of synthetic material. In particular, radiation injury may involve all layers of the chest wall, necessitating very large resections [see Figure 13a].

Muscle or omental flaps with split-thickness skin grafts may be required for coverage; thus, preoperative consultation with an experienced plastic surgeon is advisable. A particular concern is what to use to reconstruct the chest wall. Various tissues (e.g., fascia lata and ribs) have been employed, but an easier substitute that works quite well is an absorbable synthetic mesh (e.g., Vicryl). The mesh is sewn to the ribs as previously described [see Step 6, above], and the tissue flap is placed on top of the mesh, followed by a skin graft [see Figure 13b, c]. Alternatively, some authors recommend the use of muscle or myocutaneous flaps without rigid chest wall reconstruction after resection, particularly in infected fields.¹⁹

Figure 13 Chest wall resection. The presence of osteoradionecrosis may necessitate very large resections and resulting defects (a). Such defects may be covered with absorbable mesh (b), followed by an omental flap (c) or a muscle flap.

Outcome evaluation The results achieved after major chest wall resection have generally been excellent. One study reviewed 200 patients who underwent resection and reconstruction over a 25-year period.²⁰ The reconstructions ranged from relatively straightforward two-rib resections to more complex forequarter amputations. The indications for resection were lung cancer (38%), osteoradionecrosis (29%), chest wall tumor (27%), and osteomyelitis (16%). Immediate reconstruction was performed in 98% of patients. The major muscle flaps used were latissimus dorsi (20%), rectus abdominis (17%), pectoralis major (16%), and serratus anterior (9%). Free flaps were used in only 9% of cases, and split-thickness skin grafts were required in 12% of patients. Reconstruction was performed with Prolene mesh (25%), Marlex mesh (11%), Vicryl mesh (6%), or a polypropylene-methylmethacrylate sandwich (6%). Operative mortality was 7%, and major morbidity occurred in 24% of patients. Most of the morbidity was accounted for by pneumonia (14%) and acute respiratory distress syndrome (6%).

Manubrial and Clavicular Resection

Resection of the manubrium or the clavicle may be necessary if these structures become infected or involved with tumors. Clavicular and manubrial resections follow the same operative approach as other chest wall resections. Specifically, attention must be paid to how much bone to resect, how to reconstruct the defect, and how to provide tissue coverage.

Resection of sternoclavicular joint for infection

Clavicular resections are rarely performed but may be required to treat tumors, vascular compression from healed fractures, or infection. Occasionally, infections involve the sternoclavicular joint (SCJ). Patients with osteomyelitis of this joint are often immunosuppressed and may have had an indwelling subclavian vein catheter that became infected. In a study of seven patients who underwent SCJ resection for infection, five of six patients initially treated with antibiotics and simple drainage experienced recurrences, whereas six of six patients treated with resection of the joint and pectoralis muscle advancement flaps were cured. None of the patients experienced problems with arm mobility in the course of long-term follow-up.²¹

An incision is made that extends along the distal clavicle and curves down onto the manubrium. The soft tissue is divided with the electrocautery down to the clavicle and the manubrium. The muscular attachments of the pectoralis major and the sternocleidomastoid muscle are dissected off the clavicle and the manubrium with a periosteal elevator. Dissection in the subperiosteal plane is then continued circumferentially around the distal clavicle, with special care taken to keep from injuring the subclavian vessels that lie deep to the clavicle. A Gigli saw is passed around the clavicle with a right-angle clamp and used to divide the distal clavicle. The distal cut end of the clavicle is grasped with a penetrating towel clamp and bluntly dissected away from the deep tissue toward the manubrium. Any pockets of infection encountered should be cultured, drained, and débrided.

At this point, a large separation in the SCJ, caused by the infection, should be apparent. Resection of a small portion of the manubrium is usually required to remove all of the

infected bone. Once the tissue deep to the manubrium has been dissected, a small band retractor is placed beneath the manubrium, and an oscillating sternal saw is used to resect the lateral portion of the manubrium, adjacent to the SCJ. Alternatively, a rongeur may be used to débride infected bone from the manubrium. All tissue should be sent for culture.

Severe infections may necessitate more extensive resection of bone or soft tissue, but if the infection is caught early, simple resection of the SCJ is generally curative. In more extensive resections, muscle flap coverage may be required, but in simple SCJ resections, good results can be obtained by using only deep closed suction drainage, followed by multilayer closure of the wound. To prevent any recurrent osteomyelitis, antibiotics should be continued for several weeks after resection.

Resection of manubrium for cancer Manubrial resections may be required for rare cases of primary or metastatic cancers.

Because of the relative paucity of tissue overlying the manubrium, cancers in this area may involve the dermis. In such cases, it may be necessary to resect skin along with the specimen. Alternatively, if the skin is not involved, an upper midline incision may be employed. The incision is carried down circumferentially to the chest wall, with care taken to maintain a 2 to 3 cm margin from the tumor. The clavicles and ribs are divided in the same fashion as for chest wall and clavicular resections [see Figure 14a]. Associated structures (e.g., the thymus) can be resected along with the manubrium; these tumors rarely involve the innominate vein.

A polypropylene-methylmethacrylate sandwich is useful for reconstruction of this area of the chest wall [see Figure 14b]. The patch is secured to the remaining ribs and clavicles with 0 polypropylene sutures. Coverage is then provided with a pectoralis major advancement flap or, if skin was excised, a pedicled pectoralis myocutaneous flap. A pleural drain may be placed if either pleural space was entered, but this measure is not routinely employed.

Open Chest Drainage (Eloesser Flap)

Open drainage procedures are usually included in discussions of treatment of empyema, but they really represent a type of chest wall resection. Open drainage techniques for empyema were first described in the late 1800s by Poulet and subsequently by Schede. Graham, who headed the Army Empyema Commission during World War I, is credited with the observation that ensuring pleural-pleural symphysis was the key to preventing the often fatal complication of pneumothorax.²² Indications for open chest drainage include postpneumonectomy empyema or bronchopleural fistula, long-standing empyema in a patient who cannot undergo decortication, and chronic bronchopleural fistula in a high-risk patient.

Operative technique The technique currently employed by most thoracic surgeons follows Symbas's modification of Eloesser's open drainage technique.²³ This procedure has come to be known as the Eloesser flap. Preoperative chest CT is essential for identifying the exact location of the empyema, which determines the placement of the incision.

Figure 14 Manubrial resection and reconstruction. (a) The clavicles and ribs are divided as in clavicular and other chest wall resections. (b) A polypropylene-methylmethacrylate sandwich may be used to reconstruct the chest wall.

Step 1: initial incision and exposure The patient is placed in the decubitus position, and a 6 to 8 cm incision is made over the area corresponding to the most dependent area of the infected cavity. Symbas employed a U-shaped incision; however, a simple linear incision can also be used with good results. The subcutaneous tissue and muscle are then divided down to the chest wall with the electrocautery.

Step 2: resection of ribs and creation of thoracostomy The pleural space is opened with the electrocautery, any pus present is drained, and the chest cavity is manually and visually explored. Next, 6 to 8 cm segments of two or three adjacent ribs are resected according to the same principles employed for other chest wall resections. The resulting thoracostomy is large enough to permit drainage and packing. The skin overlying this thoracostomy is then marsupialized to the thickened parietal pleura with absorbable sutures [see Figure 15]. If the pleura does not possess sufficient integrity to hold the sutures, they can be placed through the periosteum of the ribs.

Step 3: packing and drainage The wound is irrigated with normal saline and packed with saline-moistened gauze. Post-operatively, a chest x-ray should be obtained to rule out pneumothorax, and twice- to thrice-daily packing is initiated. Packing is continued on an outpatient basis, and the wound is monitored. The wound will begin to close over the next several weeks. If the empyema or bronchopleural fistula has not healed by the time the wound starts closing, the thoracostomy will have to be revised. In some cases, this can be

Figure 15 Open chest drainage (Eloesser flap). Once the ribs have been resected, the skin overlying the thoracostomy is marsupialized to the parietal pleura to permit packing and open pleural drainage.

accomplished merely by manually dilating the opening in the operating room; in others, the entire thoracostomy must be revised. In either case, the goal is to maintain a large enough opening to allow adequate packing.

Step 4: closure of thoracostomy Once the lung and the pleural space have healed, the thoracostomy is closed. The procedure for closing the thoracostomy depends on the size and nature of the remaining defect [see Figure 16a]. For small defects, simple closure of the skin will suffice. For larger defects or residual spaces in the pleura, however, muscle flap closure will be required [see Figure 16b]. Improvements in radiographic techniques and greater emphasis on early intervention for empyemas have significantly reduced the need for open chest drainage; however, this technique can still be valuable in the appropriate clinical situation.

PROCEDURES FOR CHEST WALL FRACTURES/TRAUMA

A recent survey of American trauma, orthopedic, and thoracic surgeons found that the majority of polled surgeons had not performed a repair on sternal or rib fractures, nor was there a consensus of surveyed surgeons with agreed upon surgical indications. Also, a large majority were unaware of any published randomized trials addressing rib or sternal fractures.²⁴ Although rib and sternal fracture repairs have been performed for many years, the operative indications remain somewhat controversial. However, there is increasing consensus that operative fixation of these fractures is underused; therefore, basic repair techniques are discussed below.²⁵

Repair of Rib Fractures

Although there are a number of potential indications for operative repair for rib fractures, two recent randomized trials

demonstrate that patients with flail chest can benefit from operative repair in selected scenarios. Flail chest can be defined as three or more consecutive ribs fractured in two or more locations, clinically creating a segment of the chest wall that visibly demonstrates paradoxical motion with respiratory variations. In both of these trials, the operative group demonstrated a reduced number of ventilator days, intensive care unit length of stay, and lower incidence of pneumonia. One of the trials reported that more of the operative group returned to work at the 6-month follow-up compared to the nonoperative group.^{26,27} Retrospective reviews and nonrandomized cohort studies demonstrate that patients with severe flail segments without underlying pulmonary contusion are offered the greatest advantage in surgical repair of rib fractures.²⁸ Opponents to surgical correction of rib fractures suggest that the nonoperative groups were not managed with modern strategies, including epidural anesthesia and chest physiotherapy.²⁹ It is not, however, within the scope of this chapter to argue the merits of the literature surrounding the subject matter but simply to delineate some of the techniques. Other indications include chest wall defect and pulmonary hernia.

Operative planning In preoperative planning, it is useful to define the location and characteristics of all the rib fractures with a CT scan, and three-dimensional reconstruction may provide the surgeon with added information to the fracture geometry. As the main complications of the procedure are infectious in etiology, removal of chest tubes if possible, prior to the operation, is encouraged. The use of an epidural catheter for pre- and postoperative pain management should be considered. Many different techniques have been described, including variations of intramedullary fixation, plate attachment, or wiring, but the most commonly

Figure 16 Open chest drainage (Eloesser flap). (a) Photograph shows a right Eloesser flap 8 months after creation. (b) Photograph shows an Eloesser flap that was closed with a muscle flap.

employed technique is anterior plating with bicortical screw fixation.

Operative technique The patient is intubated with a single-lumen endotracheal tube or a double-lumen tube if single-lung ventilation is preferred, but this is not mandatory. The patient is placed in standard lateral decubitus positioning for a posterior lateral thoracotomy. A muscle-sparing thoracotomy incision is used if possible, and the scapulothoracic bursa is incised, giving access to the thoracic cage. This allows for fracture site localization, easily accessing ribs 3 to 9. Soft tissue immediately overlying the fractures is removed with a periosteal elevator, and the ribs are realigned with the use of bone forceps. Plates of the surgeon's selection are secured to the ribs with bicortical screw placement. Careful attention is placed to ensure that the screws are of the appropriate length to prevent screw tips from entering the pleural space. For stabilization of the chest wall, not all the fractured ribs need to be fixed. Depending on the surgeon's comfort, single-lung ventilation can be used, and by inserting a thoracoscope inferior to the fractures, the pleural space can be visualized and monitored during screw placement. Assuming that satisfactory fixation has been accomplished, the pneumothorax can be evacuated on lung reexpansion, and no chest tube would be required.

Complications Postoperative complications are primarily infectious in etiology and include superficial wound infections and empyemas. A postoperative pneumothorax should always be evaluated for on standard postoperative chest x-ray and if there is any respiratory deterioration, even if the pleural space was not entered during the procedure. Other, less frequent complications include fixation failures, chronic pain, reactive pleural effusions, and wound hematomas.

Repair of Sternal Fractures

The diagnosis of sternal fractures is usually suspected because of pain in the precordial area with tenderness and instability on palpation. There is evidence of increased diagnosis of sternal fracture in the trauma literature as a result of the increased use of CT scanning in this patient population.

However, because of the prevalence of median sternotomies in cardiac procedures, more operations for sternal fixation are performed for postoperative chronic sternal nonunion than acute fracture. Sternal fracture nonunion is commonly defined as persistent instability after 6 weeks of nonoperative management and is the most common operative indication. Other indications include fractures that create paradoxical motion with respirations altering respiratory mechanics, and a multitude of anterior plating systems are available for the surgeon to use; other techniques include placement of sternal wires through the fracture fragments.

Operative planning In the preoperative planning of surgical repair, a CT scan with three-dimensional reconstruction provides added geometric insight to the fracture pattern. In an attempt to reduce postoperative infectious complications, mediastinal or chest tubes should be removed if in place. Also, one should consider the use of an epidural catheter for postoperative pain management.

Operative technique The sternum is exposed using a previous surgical incision if present or through a longitudinal or transverse incision depending on the need for exposure. If sternal wires are in place, they are removed, and the fibrous tissue and soft tissue are removed with electrocautery and the periosteal elevator. If there is a fibrous union, this is removed as well. Once all fractures are identified, they are reduced using bone forceps. Plates are selected to allow for at least three screws to be seated on either side of the fracture. Careful attention is placed ensuring that the screws do not penetrate the inner table of the sternum. The pectus muscles are reapproximated and a drain placed to prevent seroma or hematoma formation. The drain is removed on postoperative day 1 or 2 depending on the output.

Complications Postoperative complications have a low incidence for sternal fixation procedures and are similar to rib fixation, including superficial wound infections, wound hematomas and seromas, fixation failures, chronic pain, pleural effusions, and empyemas.

10 VIDEO-ASSISTED THORACIC SURGERY

*Marcelo C. DaSilva, MD, and Scott J. Swanson, MD**

Although Sir Francis Richard Cruise has been credited with performing the first thoracoscopy for evacuation of empyema in 1865,¹ Hans Christian Jacobaeus coined the term “thoracoscopy” in an article published in 1910.² In the latter report, Jacobaeus described the use of a cystoscope to examine the chest cavity and to lyse adhesions, allowing the lungs to collapse for the treatment of tuberculosis.³ With the introduction of streptomycin, which revolutionized the treatment of tuberculosis, thoracoscopy was relegated to the occasional case report. It was not until the introduction of laparoscopic procedures in the 1980s that surgeons started to apply this technology to the thoracic cavity. In 1992, Lewis and colleagues reported 100 consecutive patients who underwent video-assisted thoracoscopic surgery, including three lobectomies with anatomic hilar dissection.⁴ From these early studies, minimally invasive video-assisted thoracic surgery (VATS) has emerged as a safe and reliable technique. It has, in many instances, supplanted standard thoracic procedures. Approximately 20% of all lobectomies now are performed thoracoscopically in the United States.⁵

Historical Background

The first single institution prospective randomized trial comparing VATS to the muscle-sparing open technique for lobectomy was published by Kirby and colleagues in 1995.⁶ Sixty-one patients undergoing lobectomy for stage I non-small cell lung cancer (NSCLC) were randomized to VATS or open thoracotomy. There was no significant difference in operating time, intraoperative complications, estimated blood loss, chest tube drainage, length of stay, or postthoracotomy pain between the groups, although it was a small study and many VATS patients had a minithoracotomy. In the early 1990s, the National Institute of Cancer funded an intergroup consortium of thoracic surgeons to investigate the efficacy of thoracoscopy and VATS in the diagnosis, staging, and treatment of intrathoracic malignancies. Cancer and Leukemia Group B (CALGB) 9335 was the first multicenter, clinical research phase II trial to look at the feasibility of treating patients with poor cardiopulmonary reserve and T1 peripheral NSCLC by VATS wedge resection or radiotherapy.⁷ This clinical trial concluded that VATS wedge resection in high-risk patients is safe and feasible. The CALGB 9380 phase II clinical trial was designed to determine the feasibility, morbidity, and mortality for thoracoscopic and/or

laparoscopic staging of esophageal cancer.⁸ One hundred seventeen patients were accrued; 82 patients (70%) met the entry criteria for thoracoscopy. Of those, 57% had positive nodes and 43% had all negative nodes. Node-negative status was confirmed on final pathology in 12 (75%) of 16 patients who underwent surgery, whereas three patients had node-positive status in the specimen (19% false negative rate). The authors concluded that thoracoscopic and/or laparoscopic staging lung and esophageal cancer was feasible and doubled the number of positive lymph nodes identified by conventional surgery.

The first multicenter prospective trial to examine standardized VATS lobectomy was CALGB 39802.⁹ One hundred twenty-eight patients were enrolled for VATS lobectomy as defined by one access incision (4 to 8 cm), two 5 mm port incisions, and no retractor use or rib spreading. The perioperative morbidity was 7.4% and 30-day mortality was 2.7%, both comparable to standards of open thoracotomy in patients with small (≤ 3 cm) peripheral NSCLC. In 1998, CALGB 39803 answered the question of restaging patients with histologic documented stage IIIA NSCLC with VATS on the basis of involved N2 nodes from mediastinoscopy prior to induction therapy.¹⁰ Seventy patients were accrued in 10 institutions. Of those, 47 patients (67%) had radiation therapy and 68 (97%) had chemotherapy. The number of incisions ranged from one to four, with a median of three incisions. VATS restaging criteria were met in 40 patients (57%): four had pleural carcinomatosis, 17 had persistent N2 disease, and 19 had three negative nodal stations. In addition, 13 (18.6%) patients in the VATS group had no evidence of persistent N2 disease attributable to unanticipated obliteration of nodal tissue. VATS was unsuccessful in 17 (24%) patients as a result of adhesions or fibrosis and tumor bulk preventing nodal access. Of the 53 patients who completed VATS restaging, 21 provided cancer tissue and 31 had histologic tissue obtained during thoracotomy; N2 downstaging occurred in 32 patients (46%). The sensitivity of VATS was 75%, the specificity was 100%, and the negative predictive value was 75.8%. No deaths occurred, but one airway injury was directly attributed to VATS. The authors concluded that VATS was feasible and provided pathologic assessment of ipsilateral nodes in treated IIIA (N2) NSCLC.

Eastern Cooperative Oncology Group (ECOG) 2202 was the first multi-institutional phase II trial to assess the feasibility of minimally invasive esophagectomy (MIE) in a multi-institutional setting.¹¹ Of 106 patients enrolled in this study, 99 underwent MIE. Anastomotic leak (7.8%) and pneumonia (4.9%) were the major complications, whereas the mortality rate was 2% (2 of 106), with a mean follow-up

* The authors and editors gratefully acknowledge the contributions of the previous authors, Raja M. Flores, MD, Bernard Park, MD, and Valerie W. Rusch, MD, FACS, to the development and writing of this chapter.

of 19 months, and the estimated 3-year survival rate for the cohort was 50% (95% confidence interval 35 to 655). The authors concluded that MIE was safe and feasible, with low perioperative mortality and morbidity and with oncologic outcomes similar to those of open esophagectomy.

The era of VATS is sufficiently mature that enough data have accrued to compare the efficacy of VATS with that of open procedures. In this regard, anatomic pulmonary resection by VATS has led to significant reductions in morbidity, mortality, and hospital length of stay, allowing patients a more expeditious return to regular activities. VATS has been used in the treatment of both benign and malignant diseases of the chest. Furthermore, VATS may be used in selected patients with early-stage lung cancer without breaching oncologic surgical principles.

DEFINITION

The terms “VATS” and “thoroscopic” refer to totally thoroscopic approaches, where visualization is dependent on video monitors, and rib spreading is avoided by using a thoracoscope, video monitors, and one to four small (1 to 2 cm) incisions.¹²

INDICATIONS AND CONTRAINDICATIONS

The indications for VATS are the same as for conventional approaches to thoracic surgery. However, tumor size greater than 6 cm, inability to tolerate single-lung ventilation, and previous thoracotomy with obliteration of the pleural space [see Table 1] are considered relative contraindications. The individual experience of the surgeon and the complexity of the operation also influence the procedures that can be performed by VATS.

PREOPERATIVE EVALUATION

The preoperative evaluation of patients undergoing VATS is similar to that of those undergoing open thoracotomy procedures. The risks related to surgical resection include perioperative morbidity and mortality and long-term functional disability. Individual patient circumstances increase or decrease the risks from standard thoracotomy resection and VATS [see Figure 1]. In addition, a discussion of the balance between the risks and benefits of surgical resection by the surgeon and the patient should also include nonstandard treatment options, such as sublobar resections, conventional radiotherapy, stereotactic radiotherapy, and radiofrequency ablation.

A thorough physical examination, past medical history, social history including tobacco smoking and exposure to arsenic and asbestos, radiologic studies (chest x-rays, computed tomographic [CT] scan, positron emission tomographic [PET]-CT scan, magnetic resonance imaging [MRI]), and pulmonary function tests are part of the preoperative preparation. Although thoracoscopic procedures tend to be less stressful than open thoracotomy, with fewer cardiopulmonary complications (e.g., atrial fibrillation or myocardial infarction),¹³ it is important to recognize that risk assessment is a complex process, and the surgeon should focus on determining the individual patient's resectability and operability. Resectability refers to the amount of lung tissue and tumor that can be safely removed without developing respiratory

Table 1 Indications and Relative Contraindications for VATS Procedures

Diagnostic indications
All biopsies: nodules, interstitial lung disease
Pulmonary infection in the immunosuppressed patient
Nodal staging of a primary thoracic tumor
Staging a primary extrathoracic tumor
Trauma: lung laceration, hemothorax diaphragmatic injury
Therapeutic indications
Lung
Spontaneous pneumothorax
Bullous disease/lung volume reduction
Persistent parenchymal airleak
Pleural effusion
Pleural disease: empyema, fibrothorax, decortication
Anatomic resection
Lobectomy
Segmentectomy
Pneumonectomy
Esophageal
Benign
Malignant
Mediastinal
VATS thymectomy for thymoma
Nodal dissection
Pericardial window
Cysts
Chest wall
Rib resection
Sarcoma
First rib for thoracic outlet syndrome
Other
Metastatectomy
Sympathectomy for hyperhidrosis
Ligation of thoracic duct
Repair/plication of the diaphragm
Relative contraindications to VATS pulmonary resection
Intolerance of single-lung ventilation
Tumor size > 6 cm
Anticipated sleeve resection
Hilar lymphadenopathy
Chest wall or mediastinal involvement
Neoadjuvant radiation therapy or chemotherapy

VATS = video-assisted thoracic surgery.

insufficiency. It depends directly on the amount of pulmonary reserve of the patient. Operability, on the other hand, refers to the ability of a patient to survive the proposed procedure and its perioperative complications. It depends on the patient's comorbid conditions. However, neither the operability of an individual patient nor the resectability of a tumor should influence the decision concerning the role of a complete resection on survival.¹⁴

Pulmonary function testing includes pulmonary spirometry, pulmonary hemodynamic response testing, and exercise testing. Pulmonary spirometry is affected by height, age, weight, sex, race, and posture, as well as arterial oxygenation and diffusion capacity. Although pulmonary spirometry and arterial oxygenation help predict mortality, they are not good predictors of postoperative complications. Diffusion capacity of the lung for carbon monoxide (DLCO) is a more sensitive predictor of postoperative complications. DLCO measures the partial pressure difference between inspired and expired carbon monoxide. It relies on the strong affinity and large absorption capacity of erythrocytes for carbon monoxide and thus demonstrates gas uptake by the capillaries that is less dependent on cardiac output.¹⁵ Thus, value is decreased in

Figure 1 Preoperative evaluation. CXR = chest x-ray; CT = computed tomographic; ECG = electrocardiogram; DLCO = diffusing capacity for carbon monoxide; FEV₁ = forced expiratory volume in 1 second; PET = positron emission tomographic; ppo = postoperative; $\dot{V}O_2$ max = maximum oxygen consumption; V/Q = ventilation-perfusion.

patients with emphysema, chronic pulmonary hypertension, and interstitial lung disease. DLCO is an important and independent predictor of postoperative complications after major lung resection, even in patients without COPD.^{16,17}

Quantitative ventilation/perfusion (V/Q) scan, along with pulmonary spirometry, is useful for predicting postoperative lung function. A calculated predictive postoperative forced expiratory volume in 1 second (ppoFEV₁ of less than 40% is associated with a 50% mortality rate. The absolute minimum ppoFEV₁ in patients undergoing lobectomy is 800 mL. Pulmonary hemodynamic response testing includes the measurement of pulmonary artery pressure and pulmonary vascular resistance. It is an invasive test and requires right heart catheterization. Systolic pulmonary artery pressure greater than 35 mm Hg is associated with a 10-fold decrease in survival rate, and pulmonary vascular resistance greater than 190 dyne is associated with a 90% mortality rate. Maximum exercise testing is concerned with the amount of arterial desaturation that occurs during exercise. Patients

with a maximum oxygen consumption ($\dot{V}O_2$ max) less than 15 mL/kg/min are considered high risk, whereas those with a $\dot{V}O_2$ max of 16 to 20 mL/kg/min could probably undergo surgery.

Flexible bronchoscopy is generally indicated in patients with hemoptysis, wheezing, and evidence of bronchial obstruction. In patients with lung cancer, bronchoscopy is always performed to assess endobronchial invasion. If a mass is found beneath the mucosa or intraparenchyma, endobronchial ultrasonography and electromagnetic navigational bronchoscopy are potential diagnostic tools, but their discussion is beyond the scope of this chapter. Bronchoscopy is also useful for the diagnosis of infectious diseases, such as tuberculosis, fungus, *Pneumocystis* pneumonia, and cytomegalovirus, prior to a thoracoscopic procedure. Finally, a multidisciplinary discussion with medical and radiation oncologists is especially useful in patients who are marginal surgical candidates and serves as a basis for discussing the proposed surgical procedure and treatment options with the patient and appropriate family or surrogates.

The goal of the preoperative evaluation is to identify those patients who can tolerate a thoracic surgical procedure. By integrating the concept of operability and resectability while achieving a complete surgical resection, along with a thorough preoperative evaluation, the surgeon will be able to identify a group of patients who would benefit from VATS.

Operative Planning

ANESTHESIA AND MONITORING

VATS is performed under general anesthesia with single-lung ventilation. A double-lumen endotracheal tube is generally used, but an endobronchial blocker may also be employed to collapse the lung. Alternatively, limited operations such as diagnostic pleuroscopy and pleural biopsy, insertion of pleural drainage catheters, or procedures performed on pneumonectomy patients can be safely done with a single-lumen endotracheal tube and intermittent lung ventilation. The degree of intraoperative monitoring needed depends on the extent of the planned procedure and on the patient's general medical condition. Standard monitoring techniques are used to measure the patient's oxygenation, ventilation, circulation, and temperature.¹⁸ Whenever indicated, a peripheral arterial line, central venous pressure and pulmonary artery (PA) catheters, and transesophageal echocardiography may be used. A Foley catheter is inserted at the beginning of the procedure to monitor urine output. Depending on the pulmonary reserve of the patient, extent of the procedure, and postoperative pain, epidural catheters can provide excellent pain relief, but they are not commonly used for thoracoscopic procedures because of the time required for insertion and frequent side effects, such as hypotension and urinary retention. Alternatively, recent studies have demonstrated the safety and efficacy of continuous infusion pumps delivering local anesthetic through a catheter in the extrapleural pocket during thoracotomy,¹⁹ as well as patient-controlled analgesia for perioperative pain management.

POSITIONING OF THE PATIENT AND PORT PLACEMENT

The general technique for VATS is neither simple nor uniform. Absolute understanding of thoracic anatomy and video orientation is critical. Thoracoscopy is made difficult by paradoxical motion when the camera and instruments are facing each other. Preparation and positioning are the same for all major VATS procedures. The surgeon stands facing the patient, who is placed in the full lateral decubitus position, elevated on pontoons [see Figure 2] designed to protect pressure points. Flexing the operating table to open the intercostal spaces (ICSs) for maneuvering instruments can be used but is not mandatory.

Port placement involves triangulation of the target with trocar ports [see Figure 3]. Alignment of the thoracoscope and positioning of the video monitors in the operating room are of paramount importance. The thoracoscope is usually placed in the seventh or eighth ICS over the mid-to-anterior axillary line [see Figure 4]. Additional 1 cm incisions, usually two, are placed along the line of the standard posterolateral thoracotomy incision approximately on the fifth ICS, one at the anterior axillary line and one at the posterior axillary line. The incisions are placed such that a triangular configuration is achieved. This setup facilitates the most efficient use of the instruments by the surgeon and the assistant. In females, the skin incision can be made in the inframammary fold for

Figure 2 Proper patient position in the operating room, with the patient propped on pontoons.

Figure 3 Triangulation technique for port placement in relation to intrathoracic structures and targets.

Figure 4 Thoracoscope and trocar placement.

cosmesis. These incision sites may vary according to the proposed procedure, the location of the pathology, patient body habitus, and previous scars. Alternatively, a ring forceps or endo-Kittner (Ethicon Endo-Surgery, Cincinnati, OH) can be used to inspect the chest cavity and expose the hilum to determine the proper position for the other incisions. The so-called access incision should be placed so as to provide direct access to the hilum. A soft tissue retractor may be used to provide adequate exposure. Intraoperative conversion to a standard thoracotomy will be necessary in approximately 5 to 20% of patients undergoing VATS depending on the level of experience for several reasons, including extensive pleural adhesions and pulmonary lesions that cannot be located thoracoscopically or that necessitate a more extensive resection than can be accomplished by VATS.

INSTRUMENTATION

The equipment used for VATS comprises (1) a video camera and tower; (2) monitors, usually two at 45° from the midline; (3) thoroscopes and ports; (4) staplers; (5) thoracic instruments (e.g., lung clamps and retractors) that have been modified for endoscopic use; (6) various devices for tissue cauterization; and (7) a suction irrigation device [see Figure 5]. A basic open thoracotomy tray and instruments should be available in the event of conversion to open thoracotomy [see Table 2].

Video Equipment

The basic components of all video systems used for thoracoscopy are similar: a large-screen video monitor, a xenon light source, a video recorder, and a printer for still photography. A second video monitor, either mounted on a cart or hanging from the ceiling, is connected by cable to the main monitor and is placed across from it at the head of the operating table. Alternatively, a single monitor can be placed at the head of the operating table. A CO₂ insufflator is used for the combined thoracoscopic/laparoscopic procedures, such as in MIE.

Thoroscopes and Thoracoports

Both rigid and flexible thoroscopes can be used for VATS. Depending on individual surgeon preference, level of expertise, and comfort zone, a 5 or 10 mm 0° or 30° rigid

telescope with a forward-viewing scope or a 5 or 10 mm flexible scope can be used. The rigid thoracoscope has an excellent resolution. Placing the video camera at the distal end of a flexible thoracoscope, as in the electronic video-thoracoscope (EVE-L, Fujinon, Wayne, NJ), yields better visualization of some relatively inaccessible areas in the chest. The disadvantages of the flexible thoracoscope include increased expense and complexity and reduced resolution compared with rigid systems.²⁰ For most VATS procedures, a 10 mm 30° rigid telescope is used. This thoracoscope allows better orientation and visualization around structures such as the pulmonary artery and bronchus. Thoracoports are shorter and have a corkscrew configuration on the outside that stabilizes them within the chest wall. The trocar is simply a blunt-tipped obturator that facilitates passage of the cannula through the chest wall. A long laparoscopic trocar may be used in morbidly obese patients. Thoracoports are available in several sizes (5, 10.5, 12, and 15 mm in diameter) to accommodate various instruments.

Staplers

Endoscopic gastrointestinal anastomosis (Endo-GIA) staplers have revolutionized the surgeon's ability to perform minimally invasive pulmonary resections. Furthermore, tissue reinforcements that buttress the staple line with prosthetic materials (Gore-Tex [W.L. Gore & Associates, Newark, DE] or bovine pericardium) are highly reliable and provide excellent hemostasis as well as closure of air leaks reducing post-operative air leakage. The vascular stapler cartridge with six rows of 2.0 or 2.5 mm staples is designed for division of thin vascular tissue such as the pulmonary vessels. Some surgeons are reluctant to use it on hilar vessels because if the stapler fails mechanically (e.g., cuts without applying both staple lines properly), life-threatening hemorrhage can ensue.²¹ Endoscopic staplers that do not cut (transverse anastomosis [TA] staplers) are also available. Some advocate using two applications of the endovascular stapling device to minimize the risk of transecting the vessel as a consequence of a

stapling misfire. In this approach, the stapler is first fired proximally with the knife removed, leaving six rows of staples in place. Next, the stapler is fired again more distally with the cutting mechanism intact to transect the vessel, leaving a total of nine rows of staples on the patient side and three rows of staples on the specimen side.

Instruments

Various types of Pennington and Duval clamps are available. Sponge sticks modified by the introduction of various curves and a line of lung clamps are used for retracting lungs, dissecting hilar structures, and holding lymph nodes. The vein retractor and the fan retractor, which can be opened and closed like a fan by turning a knob on the end, can also be used during VATS. Vein retractors are best suited for gentle retraction of hilar or mediastinal structures (e.g., vessels, bronchi, esophagus, or lymph nodes), whereas the fan retractor can be used to hold the whole lung during MIE.

In major VATS procedures (e.g., VATS lobectomy), the soft tissues of the access incision may be retracted by means of a cerebellar (or Weitlaner [Miltex, Inc, York, PA]) retractor. This allows the surgeon to dissect and encircle hilar vascular structures by using two instruments through the same incision. A Harken clamp (Scanlan, Saint Paul, MN) is useful in that it is long enough to reach behind a vascular structure, pass a silk suture to the tip of the instrument, and tie it to an endoleader to guide the stapler across these delicate arterial branches.²² A long Allis forceps is an excellent instrument for holding and retracting lymph nodes during a mediastinal lymph node dissection. Although biopsy forceps have been specifically created for laparoscopy and thoracoscopy, those used for mediastinoscopy are, in fact, well suited for thoracoscopy. Various curved and right-angle dissecting clamps, needle holders, and scissors have been developed. In addition, standard thoracotomy instruments can be inserted through a minithoracotomy incision and used just as they would be in an open procedure.

Devices for Tissue Cauterization

The standard disposable electrocautery device (Bovie Medical Corporation, Clearwater, FL) with a long tip extension, or the Harmonic Scalpel (Ethicon Endo-Surgery, Cincinnati, OH), the LigaSure vessel sealing system (Covidien, Valleylab, Boulder, CO) and the argon beam electrocoagulator handpiece are narrow enough to pass through a thoracopore. These instruments can be used for dissection and cauterization during VATS. The argon beam electrocoagulator (ConMed Corporation, Utica, NY) is a noncontact form of electrocautery that provides hemostasis on raw surfaces (e.g., denuded pulmonary parenchyma or the chest wall after pleurectomy) and helps seal air leaks from the surface of the lung. Instrumentation for videothoracoscopy continues to evolve. Nevertheless, it may still be necessary to combine disposable and nondisposable instruments from different manufacturers and to use instruments originally designed for other procedures. It is best to maintain a single standard tray that includes the basic instruments required for most operations and to add instruments as needed.

Basic Operative Technique

At our institution, VATS is conducted under general anesthesia using a double-lumen endotracheal tube and

single-lung ventilation. The patient is placed in the full lateral decubitus position, but depending on the location of the target, the patient can be tilted 5° forward or backward. Ventilation to the lung being operated on is stopped as soon as the patient is rotated into the lateral decubitus position, to ensure that the lung will be thoroughly collapsed by the time the videothoracoscope is inserted into the pleural space. The incisions are made on the superior aspect of the ribs to avoid injury to the neurovascular bundle. A standard thoracoscopy is performed with three 10 mm incisions: a camera port is placed in the anterior axillary line in the seventh or eighth ICS; an anterior or access port is placed between the latissimus dorsi and the pectoralis major muscles in the fourth or fifth ICS, and a posterior or working port is placed adjacent to the scapula in the fifth or sixth ICS. Alternatively, a 5 mm incision can be used for a 5 mm camera, and one working port ranging from 3 to 10 mm can be used. It is important to orient the instruments and the thoracoscope such that they face the target within a 180° arc; this positioning prevents mirror imaging and helps the surgery team develop a three-dimensional spatial anatomic orientation in the chest. The incisions should also be placed widely distant from each other so that the instruments do not crowd one another. Should it become necessary to convert to a thoracotomy, the two upper incisions can be incorporated into the thoracotomy incision and the lower incision can be used as a chest tube site. When a patient is being operated on for an apical lesion, the camera port can be placed at the fifth or sixth ICS, and the two instrument ports may also be moved higher, toward the axilla, and the other higher on the posterior chest wall at approximately the third ICS. Also, a fourth port may be helpful for the introduction of additional instruments or to palpate the lesion, depending on its location. An infant Finochietto (Medicon, Bedford, VA) or a Weitlaner retractor is used to keep the soft tissues from falling into the wound without spreading the ribs. These are the basic steps on which modification of the technique will occur depending on the pathology, the location of the target being removed, and the surgeon's skills.

VATS Procedures for Pleural Disease

OPERATIVE TECHNIQUE

One or two 10 mm incisions are made for the videothoracoscope and instruments. The videothoracoscope is inserted through either a 5 or 10 mm thoracopore at the seventh or eighth ICS in the midaxillary line. In cases of pleurodesis, either by mechanical or talc poudrage, the incisions are used for placement of chest tubes, with a right-angle tube inserted over the diaphragm through the lower incision and a straight tube advanced up to the apex of the pleural space through the upper incision. Alternatively, a small 19 French Silastic flexible drain (Blake drain, Ethicon, Somerville, NJ) can be placed in the chest cavity as well, but it has to be looped around the base of the lung and over the diaphragmatic surface and guided posteriorly along the parietal pleura with its tip up in the apex.²³ Special attention must be paid to the placement of the incision in patients with suspected malignant mesothelioma because of the propensity of this tumor to implant in incisions and needle tracks. Once the videothoracoscope has been inserted, pleural fluid is drained with

Yankauer suction tip (Cardinal Health, Dublin, OH) and is sent for cytology, microbiology, and chemistry. Inspection of the cavity is performed, and multiple pleural biopsies are obtained. Fibrinous debris can be removed by irrigating the pleural space with a pulsating water irrigation system. This technique is particularly useful for the débridement and drainage of loculated fibrinopurulent empyema. Talc pouddrage for the treatment of malignant pleural effusion can be accomplished by delivering 2 to 6 g of talc in the pleural cavity with a pneumatic atomizer using 10 L of high-flow O₂.²⁴ At the end of the procedure, an intercostal nerve block is performed under the direct vision of the thoracoscope.

TROUBLESHOOTING

In patients with loculated effusion, the thoracoport placement must sometimes be modified. The preoperative chest CT scan should help ensure that the ports are placed in areas where the lung is not adherent to the chest wall. In some cases, the pleural space is obliterated by adhesions or tumor. This event occurs most frequently in patients who have had severe inflammatory disease (e.g., pneumonia, empyema, or tuberculosis) or extensive pleural malignancy (e.g., locally advanced malignant mesothelioma). In these circumstances, the anterior thoracoport incision can be extended to a length of 5 to 6 cm, the underlying rib section can be resected, and the parietal pleura can undergo biopsy. If thoracotomy is subsequently warranted for therapeutic reasons (e.g., for pleurectomy, decortication, or extrapleural pneumonectomy for mesothelioma), this small incision can be incorporated into the thoracotomy incision.

VATS Pulmonary Wedge Resection

VATS pulmonary wedge resection has become a standard approach to diagnosing small, indeterminate pulmonary nodules and pulmonary infiltrates of uncertain origin, particularly in immunocompromised patients in whom transbronchial biopsy is neither safe nor appropriate. The role of VATS wedge resection is less well defined in the management of primary lung cancers but may be indicated in patients with marginal lung function who otherwise would not tolerate a lobectomy. Although no prospective studies have been performed to clearly assess the benefit of pulmonary metastasectomy, there is an abundance of retrospective data to indicate a long-term survival benefit from complete pulmonary resection. The general criteria in selecting patients for pulmonary metastasectomy include the following: (1) the primary neoplasm must be completely controlled or imminently controllable; (2) metastatic lesions must be limited to the lung without evidence of other distant organ involvement; (3) all metastases must be resectable with adequate pulmonary reserve; and (4) nonavailability of another effective therapy. In cases that meet these resection criteria, long-term survival rates have been reported to be in the range of 30 and 58% for patients with soft tissue and osteogenic sarcomas, respectively. Similar cure rates have been reported with the resection of isolated pulmonary metastases from colon cancer (30.5%), renal cell carcinoma (52.4%), head and neck cancers (48%), and germ cell tumors (59%). Although some melanoma patients with a solitary metastasis may benefit from pulmonary metastasectomy, most patients with this disease do not survive long-term despite aggressive resection of

the metastasis.²⁵ Improved survival in patients with pulmonary metastases appears to be directly linked to the ability to remove all macroscopic tumor. The biology of pulmonary metastases may favor VATS resection based on the following arguments: (1) metastases have been present prior to treatment of the primary lesion and in that sense have been “missed” for a significant period of time already; (2) as noted above, multiple resections do not adversely affect the overall outcome of patients with metachronously detected metastases; (3) patients with unresectable disease who have a recurrence will not be subject to a larger operation, i.e., thoracotomy; (4) VATS resection may be less stressful for patients and therefore result in less immunosuppression, resulting in a more favorable disease course; and (5) VATS may permit patients to return to their regular work or family schedules significantly earlier than an open approach. Other considerations include quality of life and cost of treatment. Historical data, tumor biology, and recent advances in radiologic and surgical techniques support the use of video-assisted surgery in the resection of pulmonary metastases, following the paramount principle of removing all lesions found on a high-resolution CT scan.

Anecdotal reports of port-site recurrence also have raised concerns about VATS as a treatment method in patients with malignancies. However, a 2001 study of 410 patients from a prospective VATS database found only one case of port-site recurrence.²⁶ The authors concluded that the incidence of such recurrences could be kept low if surgical oncologic principles are respected. These principles include (1) reserving VATS for lesions that can be widely excised; (2) conversion to an open thoracotomy for definitive or extensive operations; and (3) meticulous technique for extraction of specimens from the pleural space, with small specimens removed directly through a thoracoport and larger specimens removed in an endo-bag.

OPERATIVE TECHNIQUE

Once general anesthesia has been induced and a double-lumen endotracheal tube inserted, the patient is placed in the full lateral decubitus position. Small subpleural pulmonary nodules are most easily identified in a fully atelectatic lung because they protrude from the surrounding collapsed pulmonary parenchyma. Most pulmonary wedge resections are performed as true videothoroscopic procedures using just three port incisions placed in a triangulated manner [see Figure 4]. The pulmonary nodules to be removed are grasped with an endoscopic lung clamp (Pennington, ring forceps, or Duval) inserted through one instrument port, and wedge resection is done with repeated applications of an endoscopic stapler inserted through the opposite port. An endoscopic lung compression clamp is a linear clamp that can be placed deep to the lesion to ensure a 1 cm margin from the lesion to the staple line [see Figure 6]. As the resection is performed, it is often helpful to introduce the stapler through each of two instrument ports to obtain the correct angle for application to the lung. To prevent tumor implantation in the chest wall, all specimens are placed in a disposable endo-bag and brought out through a slightly enlarged anterior thoracoport incision. At the end of the procedure, intercostal nerve blocks are performed under direct vision of the thoracoscope, and a single chest tube is inserted through the inferior port after the videothoracoscope is withdrawn.

Figure 6 Wedge resection, lung compression clamp.

TROUBLESHOOTING

Several techniques may be used to locate pulmonary nodules that are either too deep or too small to be easily visible on simple inspection of the lung. All of these should be used in conjunction with a high-quality preoperative chest CT scan to identify the lung segment in which the nodule is located. Thoracoscopic examination of the lung nodule can be performed by gently running an endo-Kittner or a ring forceps on the surface of the lung as a surrogate to digital palpation. With experience, one can “feel” a bump and grasp the visceral pleura adjacent to the location. The nodule can be brought up toward the examining finger placed through one of the ports. Alternatively, under prior CT guidance preoperatively, a needle may be inserted into the nodule for intraoperative localization, much like a breast needle localization procedure. Localization is accomplished by injecting methylene blue or by inserting a barbed mammography localization needle, which is then cut off at the skin exit site and later retrieved thoracoscopically. Needle localization techniques are effective, but they also are costly and time-consuming and need to be coordinated with the radiology team and surgeons. Finally, if careful endoscopic examination of the lung fails to reveal the location of a nodule, an access incision is added to the videothoracoscopy. Each lobe of the lung is sequentially rotated up to this non-rib-spreading utility thoracotomy for direct digital palpation. This technique almost always permits identification of a nodule when other techniques fail.

Pulmonary nodules located on the broad surface of the lung may not be amenable to a wedge resection with an endoscopic stapler. Such nodules can be removed by means of electrocauterization, just as in an open thoracotomy. An extension is placed on the handle of the electrocautery device, which is then introduced into the pleural space through either a port or an access incision. Another approach is to resect the pulmonary nodule with a laser in either contact or noncontact mode. To minimize bleeding and air leakage, raw pulmonary

surfaces can be cauterized with either the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser or the argon beam coagulator. Numerous types of absorbable sealant patches or materials are also available to control air leaks from areas of raw pulmonary parenchyma.

Occasionally, after a wedge resection, it is necessary to suture together the pleural edges over an area of raw pulmonary parenchyma. The suturing can be done directly through a non-rib-spreading access incision or through port sites. In the latter case, the ports are removed and a 3-0 polypropylene suture is passed through the anterior port site with a standard needle holder. A second needle holder is introduced via the posterior port site and used in place of a forceps to pick up and reposition the needle as it is passed through the lung. The surgeon and the first assistant work together to oversee the lung, in contrast to the normal practice for an open procedure, in which the surgeon uses a needle holder and a forceps to place the sutures.

VATS Procedures for Spontaneous Pneumothorax and Bullous Disease

OPERATIVE TECHNIQUE

VATS is now frequently performed for the management of recurrent spontaneous pneumothorax and for bullous disease. The approach is similar to that followed in a wedge resection, with three or four port sites being used. The videothoracoscope is inserted at the fifth ICS in the midaxillary line, and two other port sites are added at the fourth ICS in the anterior and posterior axillary lines. In patients with spontaneous pneumothorax, the responsible bulla (which is usually apical in location) is identified, and wedge resection is done with a tissue-reinforced endoscopic stapler. Bullae can be excised by applying the stapler across the base of the area of bullous disease. They also can be ablated with the argon beam coagulator or the Nd:YAG laser and then suture-plicated if necessary.

TROUBLESHOOTING

The placement of port incisions should be determined by the location of the bullae. Because bullous disease is generally apical, port sites are correspondingly higher than for the average wedge resection (i.e., at the fourth and sixth ICSs rather than at the fifth or sixth and eighth ICSs). The precise placement should, however, be determined by determining the exact location of the disease site(s) on the preoperative CT scans. The main problem after resection for bullous disease is prolonged air leak from the staple line. This problem can be minimized by applying commercially available sleeves made of bovine pericardium or with tissue-reinforced staplers and by performing pleurodesis. Mechanical pleurodesis is done with a small gauze sponge passed through a port site. Some surgeons scarify the pleura by cauterizing it with the argon beam coagulator or the Nd:YAG laser, but this is not as effective as mechanical pleurodesis. Chemical pleurodesis by talc poudrage should be reserved for older patients with emphysema and bullous disease and avoided in young patients with spontaneous pneumothorax, who might require a thoracotomy later in life. Another option in younger patients is a limited apical pleurectomy. Special angulated instruments

and blunt dissectors have been designed for this procedure; however, a parietal pleurectomy is also easily performed with combinations of standard blunt and sharp instruments.

VATS Lung Volume Reduction Surgery

OPERATIVE TECHNIQUE

VATS may also be applied to the performance of lung volume reduction surgery (LVRS). If unilateral LVRS is planned, the patient is placed in the lateral decubitus position, and port placement is similar to that for a patient undergoing a wedge resection of the upper lobe. Most patients undergoing LVRS, however, benefit from bilateral LVRS. For this procedure, the patient is placed in the standard supine bilateral lung transplantation position, with shoulder rolls placed vertically in an inverted U fashion behind the back and with the arms positioned above the head. The camera port is placed in the anterior axillary line at the sixth ICS. A lung compression clamp is placed on the area that will be resected. A tissue-reinforced stapler is then inserted into the chest and fired sequentially until the desired area is excised [see Figure 7].

TROUBLESHOOTING

A major cause of morbidity and mortality with this procedure is the occurrence of air leaks, which sometimes are large enough to compromise ventilation significantly. Thus, once LVRS has been done on one side, the lung is reexpanded and any air leaks are carefully assessed. If the leak is small, the other side is operated on in the same setting; if the leak is large, the contralateral procedure is postponed to a later date. The use of fibrin glue or another commercially available pneumostatic sealant along the staple line should be considered to minimize postoperative air leakage.

VATS Lobectomy and Pneumonectomy

Although VATS lobectomy is much less frequently performed than VATS pulmonary wedge resection, standard

techniques have been developed.²⁷ VATS pneumonectomy is performed with less frequency. There are emerging data using VATS, but this approach is experimental at this point in time. These tumors are usually larger and centrally located, making it difficult to assess for the option of a sleeve lobectomy. Therefore, this operation is best performed through an open thoracotomy. However, these operations are done as VATS procedures using an access incision, which facilitates insertion of standard thoracotomy instruments, extraction of the resected specimen from the pleural space, and performance of the technically complex aspects of the procedure, including dissection of the hilar vessels and the mediastinal lymph nodes.

Two approaches to lobectomy have been developed. One involves sequential anatomic ligation of the hilar structures, much as in a standard anatomic lobectomy, and the other involves mass ligation of the pulmonary vessels and the bronchus. The latter is not considered an anatomic lobectomy; therefore, we do not endorse its practice. Both approaches require at least two port incisions in addition to the access incision. The sequential anatomic ligation approach has been well described and follows sound surgical oncologic principles. Accordingly, it is our preferred method of performing VATS lobectomy. In an effort to standardize the approach, we define a VATS lobectomy as an anatomic dissection that is performed entirely under thoracoscopic visualization, proceeds in an anterior-to-posterior fashion, and uses a 4 cm utility incision, two thoracoscopy ports (one for the camera and one for retraction), and no rib spreading. Avoiding rib spreading is the key element in VATS lobectomy to prevent postoperative pain and trauma to the intercostal nerve bundles, which are responsible for the postthoracotomy pain syndrome. A metastatic survey is performed in all patients undergoing VATS lobectomy for malignant disease. The chest is inspected for metastatic pleural and pericardial implants and effusion, chest wall invasion, adhesions, enlarged lymph nodes, and anatomic variations. Radical lymph node dissection includes evaluation of lymph node levels 2, 4, 7, 8, and 9 on the right side. On the left side, it should also include lymph node levels 5 and 6.

OPERATIVE TECHNIQUE

Lobectomy (Sequential Anatomic Ligation)

Correct positioning and port placement are essential for a successful VATS lobectomy. The first port placed is the camera port. It is usually placed through the seventh or eighth ICS and should provide visualization of the anterior and posterior hilum and align with the major fissure in a caudal-cephalic orientation. Whether the port is in the anterior, middle, or posterior axillary line depends on the level of the diaphragm as seen from a review of the preoperative chest x-ray or CT scan, on the location of the target, and on the side of the procedure.

The anterior or utility port (< 4 cm) should be placed right over the hilum. The hilum and the fissures will be dissected through this port. The port usually is created anterior to the latissimus dorsi in the fourth ICS for upper lobectomies and in the fifth ICS for lower lobectomies. A soft tissue retractor may be used to keep the subcutaneous tissue and muscle away from the incision. The third (posterior) port is usually

Figure 7 Tissue-reinforced stapler is inserted into the chest.

placed where the edge of the lower lobe touches the diaphragm under the vision of the thoracoscope either inferior or posterior to the scapular tip. This port usually is used for retracting the lung. A ring forceps is placed through the posterior port, and the upper lobe is retracted laterally to permit visualization of the superior pulmonary vein. Table 3 shows the general operative steps for VATS lobectomy.²⁸

Right-Side Resections

Right upper lobectomy The initial dissection is carried out at the anterior hilum. The phrenic nerve is identified, and the mediastinal pleura is opened posterior to it. This plane is developed anteriorly, superiorly, and then posteriorly between the lung and the azygos vein. If any level 10 lymph nodes are found at this location, they are sampled and sent for frozen section. This dissection can, for the most part, be accomplished with blunt dissection using two endo-Kittners. Next, the lung is retracted anteriorly and the posterior hilum is opened to expose the right mainstem bronchus. Further dissection is carried out to expose the bifurcation of the upper lobe bronchus and the bronchus intermedius. The superior pulmonary vein is dissected from the overlying pleura via the access incision with long Pearson or Metzenbaum scissors and DeBakey forceps, similar to an open lobectomy. A Harken clamp is passed behind the superior pulmonary vein after clear identification of the middle lobe vein. The superior pulmonary vein is encircled with an oiled 2-0 silk suture, which is then tied to the endoleader.²⁹ A lung clamp is placed through the utility incision, and the upper lobe is retracted posteriorly. An endovascular stapler is placed through the posterior port and, guided by the endoleader, is passed behind the superior pulmonary vein and deployed [see Figure 8].

Once the pulmonary vein has been divided, the truncus anterior of the pulmonary artery and its variable apical branches are exposed. A Harken clamp is passed around the anterior and apical pulmonary arterial branches, and an oiled 2-0 silk suture followed by the endoleader is passed around these vessels and brought out through the utility incision. The endovascular stapler is passed through the posterior port and used to transect the vessels. Transection of the truncus artery and its branch exposes the right upper lobe bronchus [see Figure 9]. Dissection is performed to separate the ongoing pulmonary artery from the bronchus. An endoscopic 4.8 mm GIA stapler is placed through the posterior port and closed but not fired until the lung is inflated, demonstrating that the middle lobe bronchus is patent. Once the upper lobe bronchus has been divided [see Figure 10], the fissure is completed with the stapler. The upper lobe is then placed in a large surgical tissue endo-bag and removed via the utility incision.

Figure 8 The endoleader looped around the superior pulmonary vein.

Figure 9 The endoleader looped around the truncus anterior and its branch.

Certain basic surgical concepts—dissection of hilar structures, passage of a monofilament suture around the structure, and transection with a stapler—are similar for all lobectomies. However, the order in which structures are transected and the ports through which staplers are passed differ.

Right middle lobectomy The camera port is placed in the seventh ICS in the midaxillary line. The anterior or access port is placed in the fifth ICS. The posterior or working port is placed either at the scapula tip or posterior to it in the sixth or seventh ICS. The right middle lobe is retracted laterally, and the middle lobe vein is exposed by dissecting it on the anterior hilum. Once the middle lobe vein is dissected free, it is divided using the same maneuvers as described earlier

Table 3 Operative Steps for VATS Lobectomy

VATS = video-assisted thoracic surgery.

Figure 10 Division of the upper lobe bronchus.

using the endovascular stapler. The middle lobe bronchus is exposed and divided before the artery because it lies anterior to the pulmonary artery to the middle lobe. Caution should be exercised while dissecting around the middle bronchus so as not to injure the arterial branches to the middle lobe. Maciejewski described two arterial branches of the pulmonary artery to the middle lobe in 57% of the patients and a single artery penetrating the middle lobe in 43% of patients.³⁰ The length of arteries can be up to 30 mm and the diameter up to 10.6 mm. The pulmonary artery branches are dissected free, isolated, and divided with the endovascular stapler. The fissure is completed, and the middle lobe is removed in a specimen endo-bag through the access port.

Right lower lobectomy The camera port is inserted in the seventh ICS in the posterior axillary line. The posterior port is placed either at the tip of the scapula or immediately behind it. The access port is placed directly over the fissure between the middle and lower lobe at the level of the inferior pulmonary vein. Ring forceps are used to retract the middle lobe medially and the lower lobe posteriorly. Next, the lower lobe is retracted superiorly and the inferior pulmonary ligament is taken down with either electrocautery device (Bovie) or Harmonic shears (Ethicon Endo-Surgery, Cincinnati, OH). Level 9 lymph nodes are taken during this step of the operation. Next, the posterior mediastinal pleura is opened at the level of the inferior pulmonary vein and the dissection continues posteriorly between the posterior hilum and the esophagus. If a level 8 lymph node is found at this location, it is removed as well. This dissection is carried out to the level of the azygos vein. The lung is then retracted anteriorly toward the anterior mediastinum. Next, level 7 (subcarinal) lymph nodes are dissected with two endo-Kittner dissectors and removed. At this point, most of the pleura along the

hilum has been opened posteriorly and the inferior pulmonary vein dissected. Next, the apex of the lung is gently grasped with a ringed forceps and retracted toward the diaphragm. This maneuver exposes the paratracheal lymph nodes. The pulmonary artery is then identified just under the surface of the pleura at the fissure. The visceral pleura overlying it is opened. A tunnel of visceral pleura is created over the pulmonary artery by gently pulling the visceral pleura toward the chest wall and dissecting it with endo-Kittners. This maneuver allows for identification of the middle lobe bronchus. Once this tunnel is developed, the fissure is completed posteriorly with the endo-stapler. At this point, the lower lobe pulmonary artery is visualized. A Harken clamp is passed under the artery, and the artery is dissected. The flat tip of a 35 mm vascular load stapler (white load) is passed under the pulmonary artery to the lower lobe and the basilar trunk is transected. The lung is retracted upwards and toward the anterior mediastinum. The inferior pulmonary vein is then transected with the same technique as for the pulmonary artery. The vascular stapler is brought in from the access incision toward the back while lifting the lung up with the ring forceps through the posterior port. The lung is then pulled upwards, the lower lobe bronchus is dissected out, and the stapler is applied but not fired. The anesthesiologist should then inflate the middle lobe. Bronchoscopy is also performed, and the orifice to the middle lobe is visualized. Only after these maneuvers have been performed is the bronchus to the lower lobe transected. The lobe is placed in the endo-bag and brought out through the access port incision.

Left-Side Resections

Left upper lobectomy The left upper lobectomy is technically the most challenging approach because of the anatomic variability in the pulmonary artery branches as well as a common pulmonary vein trunk that drains to the back of the left atrium. Maciejewski reported that in most cases of his series, there were four, and, in a few cases, up to seven, branches of the pulmonary artery to the upper lobe, measuring 30 mm in length and 12 mm in diameter.³¹ In about 50% of the cases, the branches were divided in (a) apicoanterior trunk, (b) lingular, and (c) one or two subsegmental branches. In 25% of the cases, almost all segmental branches penetrated into the lobe separately. In 20% of the cases, a single apicoposterior trunk or independent segmental or subsegmental branches were present. Only in 5% of the cases did the branches include the apicoposteroanterior trunk and the remaining segmental and subsegmental branches.

Although port placement is similar to that for right upper lobectomy, the camera port is placed more posteriorly through a seventh or sixth ICS in the anterior axillary line, to avoid obstruction of the camera view by the heart and the pericardial fat pad. Once all ports have been placed, dissection of the anteroposterior window lymph nodes is carried out. This provides information about metastatic nodal spread. It also opens up the space around the artery and vein. The posterior port is placed just behind the tip of the scapula. The lung is retracted posteriorly, the hilum is opened anteriorly, and the superior pulmonary vein is dissected free. Caution must be exercised during this phase of the dissection to avoid injuring the back wall of the vein while it is being dissected off the

airway. The upper lobe is retracted posteriorly and the lower lobe is retracted somewhat anteriorly, toward the pericardium, splaying out the fissure. The pulmonary artery is usually found in the fissure, where it is visualized as a white, shiny structure. Dissection of the pulmonary artery creates a space on the top of the artery, a so-called vascular tunnel that allows one to complete the fissure with a stapler, thereby avoiding problems with air leak. A ringed forceps is placed through the fourth ICS to access the incision anteriorly. The lung is now moved anteriorly. The endo-Kittners are placed through the posterior port to dissect the lymph nodes located above the pulmonary artery as it traverses into the fissure. The first apical branch of the pulmonary artery is dissected free and transected with an endoscopic GIA vascular stapler introduced via the posterior port. The anterior aspect of the fissure is opened with one or two applications of an endoscopic GIA stapler introduced via the access incision. The bifurcation of the left upper and left lower lobe bronchi is identified, and the left upper lobe bronchus is transected with an endoscopic GIA stapler with 4.8 mm staples introduced via the posterior port. A ringed forceps is used to retract the stump of the bronchus laterally, which facilitates exposure of several branches of the pulmonary artery, including the lingular artery. These branches are transected individually via the posterior port. The fissure is completed with an endoscopic GIA stapler with 4.8 mm staples through the posterior port and dividing it. The lobe is placed in the endo-bag and brought out through the access port incision. A 24 French chest tube is placed toward the apex of the lung.

Left lower lobectomy The camera port is placed in the eighth ICS in the posterior axillary line to provide exposure to the posterior hilum and to avoid crowding of the instruments. The access port is placed anteriorly in the fifth ICS. The posterior working port is usually posterior to the scapular tip in the sixth or seventh ICS. First, the lung is retracted superiorly and the inferior pulmonary ligament is identified and level 9 lymph nodes are sampled. The left lower lobe is held superiorly with a ring forceps through the posterior port, with the ligament under tension. A long-tipped electrocautery device, or ultrasonic scalpel, divides the ligament at the base of the inferior pulmonary vein. Next, the inferior pulmonary vein is completely dissected. Once the inferior pulmonary vein has been dissected free, an endoscopic GIA vascular stapler is placed via the utility incision to transect the vessel. The interlobar pulmonary artery is isolated within the fissure. The branches of the pulmonary artery to the left lower lobe are of three types: trunk, segmental, and subsegmental. In 70% of the cases, the branches penetrating the basal segments showed a treelike configuration; in 3% of the cases, the segments had a bushlike configuration; and in 27% of the cases, the branches had an intermediate anatomic configuration.³² The basilar trunk and the artery to the superior segment are identified, dissected, and divided with the endovascular stapler. The superior segmental artery is divided first and the basilar trunk next. This strategy avoids injury to the superior segmental branch with the stapler used to divide the basilar branches. Finally, the bronchus to the lower lobe is dissected and divided with an endo GIA 4.8 mm stapler through the access incision. Attention must be paid

to avoid impingement on the lingular bronchus. In cases of incomplete fissure, the fissure between the lingula and lower lobe should be opened prior to dissection of the pulmonary artery to facilitate subsequent arterial exposure.

Pneumonectomy

This operation is best performed through an open thoracotomy.

VATS Mediastinal Lymph Node Dissection

OPERATIVE TECHNIQUE

For biopsy of the aortopulmonary window nodes or anterior mediastinal masses, VATS mediastinal lymph node dissection is often performed as an alternative to a Chamberlain procedure and is thought by some surgeons to provide better exposure and a superior cosmetic result. The thoracoscope is inserted at the fifth or sixth ICS in the posterior axillary line. Instruments for retracting the lung inferiorly are introduced via a port at the seventh ICS in the midaxillary line. Instruments for dissecting nodes are introduced through ports placed at the fourth ICS in the anterior axillary line and in the auscultatory triangle. The lymph nodes are dissected free with graspers (e.g., curved sponge sticks or polyp forceps), scissors, the electrocautery device, and endoscopic hemostatic clips. A similar approach can be used for biopsy of other mediastinal nodes, including the paratracheal and periesophageal nodes. Dissection of level 4 and level 2 nodes on the right is facilitated by transection of the azygos vein. It is more difficult to do a complete en bloc subcarinal lymph node dissection on the left than on the right with this method, although nodal sampling of this region by means of VATS is certainly feasible, especially when an access incision is used.

TROUBLESHOOTING

Care should be taken not to injure the phrenic nerve as it courses along the superior vena cava on the right and across the anterior aspect of the aortopulmonary window on the left. The vagus nerve should be visualized and the origin of the recurrent laryngeal nerve avoided during dissection. The recurrent laryngeal nerve is easily injured on the left side, where it passes around the ligamentum arteriosum before traveling under the aortic arch; however, it can also be injured on the right side if mediastinal lymph node dissection is carried too high superiorly along the origin of the innominate artery.

It is unwise to perform a VATS mediastinal lymph node dissection after induction chemotherapy or chemoradiotherapy because the lymph nodes will often be densely adherent to surrounding structures. This is especially true on the right side, where the superior mediastinal lymph nodes usually adhere densely to the superior vena cava, the azygos vein, and the right main pulmonary artery. A thoracotomy, with extensive exposure and sharp dissection, is usually required for a safe and complete mediastinal lymphadenectomy.

All lymphatic branches should be ligated during node biopsy or dissection to prevent a chyle leak. There are often large lymphatic branches in the distal right paratracheal area. In addition, the thoracic duct can be injured if periesophageal or posterior mediastinal lymph nodes are being removed.

VATS Esophagectomy

OPERATIVE TECHNIQUE

Transthoracic Approach

The most widely accepted method of performing a thoracoscopic and laparoscopic esophagectomy is the technique developed by Luketich and colleagues.³³ All patients undergo bronchoscopy and on-the-table esophagogastroduodenoscopy (EGD) to make a final assessment of the location of the tumor and the suitability of the gastric conduit for reconstruction. If the EGD, endoscopic ultrasonography, or CT scan findings suggest gastric extension, T4 local extension, or possible metastases, we perform a staging laparoscopy, a thoracoscopy, or both. Patients are intubated with a double-lumen tube and placed in the left lateral decubitus position. The surgeon stands on the right and the assistant on the left. Four thoracoscopic ports are used [see Figure 11]. A 10 mm camera port is placed at the seventh to eighth ICS, just anterior to the midaxillary line. A 5 mm port is placed at the eighth or ninth ICS, posterior to the posterior axillary line, for the Harmonic shears. A 10 mm port is placed in the anterior axillary line at the fourth ICS; this port is used to pass a fan-shaped retractor to retract the lung anteriorly and allow exposure of the esophagus. The last 5 mm port is placed just posterior to the scapula tip; it is used to place instruments for retraction and countertraction. In most patients, a single retracting suture (0-Endostitch, US Surgical, Norwalk, CT) is placed near the central tendon of the diaphragm and

Figure 11 Thoracic port placement for minimally invasive esophagectomy.

brought out through the inferior anterior chest wall through a 1 mm skin incision, providing downward traction on the diaphragm and allowing exposure of the distal esophagus.

The intrathoracic esophagus is exposed by dividing the inferior pulmonary ligament. The mediastinal pleura overlying the esophagus is opened, and dissection is carried out cephalad toward the azygos vein. The azygos vein is divided with an endoscopic stapler [see Figure 12]. Care is taken to preserve the mediastinal pleura above the azygos vein. This maneuver helps to maintain the gastric tube in the posterior mediastinum. By keeping the mediastinal pleura intact near the thoracic inlet, it may help to seal the plane around the gastric tube, preventing downward extension of a cervical leak into the chest. Circumferential mobilization of the esophagus is performed up to the level of 1 to 2 cm above the carina, including all surrounding lymph nodes; periesophageal tissue and fat; the plane along the pericardium, aorta, and contralateral mediastinal pleura up to but not including the thoracic duct; and the azygos vein laterally. Esophageal branches of the aorta are cut with a Harmonic scalpel. No effort is made to find the thoracic duct. A Penrose drain is placed around the esophagus to facilitate traction and exposure [see Figure 12].

The entire intrathoracic esophagus is mobilized from the thoracic inlet to the diaphragmatic reflection. As the dissection proceeds toward the thoracic inlet, care is taken to stay near the esophagus to avoid trauma to the posterior membranous trachea and the recurrent laryngeal nerves. Once the esophagus is completely mobilized in the chest, a single 28 French chest tube is inserted through the most anterior and inferior port and the lung is inflated to search for any air leaks from the trachea and proximal bronchus. The thoracic ports are closed, and the patient is turned to the supine position. The surgeon remains on the patient's right; the patient is positioned in the steep reverse Trendelenburg position.

Five abdominal ports (four 5 mm and one 11 mm) are used for the dissection [see Figure 13]. The gastrohepatic ligament is divided. The right and left crura of the diaphragm are dissected; division of the phrenoesophageal membrane is avoided at this stage of the operation because this may cause loss of the pneumoperitoneum into the chest cavity and lead

Figure 12 Stapling of the azygos vein.

Figure 13 Abdominal port placement.

to technical difficulties. The stomach is mobilized by dividing the short gastric vessels using the Harmonic scalpel. The gastrocolic omentum is divided, with care taken to preserve the right gastroepiploic arcade [see Figure 14]. The stomach is

Figure 14 Division of the gastrocolic omentum along the greater curvature of the stomach and dissection of the hiatus.

retracted superiorly, and the left gastric vessels are identified. The left gastric artery and vein can be divided from the retrogastric or lesser curve view, depending on the anatomy, using the Endo-GIA stapler.

PYLOROPLASTY

The Harmonic scalpel is used to open the pylorus, and the Endo Stitch (2.0, US Surgical) is used to close the pylorus transversely [see Figure 15]. A gastric tube is then constructed by dividing the stomach starting at the lesser curvature and preserving the right gastric vessels with the 4.8 mm stapler (Endo-GIA II, US Surgical) [see Figure 16]. There is some variability in the construction of the gastric tube based on the characteristics of the tumor. It may be necessary to construct a slightly more narrow tube or to resect some of the proximal stomach in tumors with significant gastric extension. If gastric extension of the tumor is significant, the resection of the stomach is larger and an intrathoracic anastomosis is performed. Currently, we prefer a gastric tube of 5 to 6 cm in diameter. Extreme caution must be used when manipulating the gastric tube during mobilization and stapling to avoid trauma. The most cephalad portion of the gastric tube is then attached to the esophageal and gastric specimen using two 2-0 endo-sutures. An additional superficial stitch may be placed on the anterior proximal gastric tube to facilitate orientation and prevent twisting as the tube is brought up into the neck [see Figure 17]. A feeding jejunostomy tube is done laparoscopically. First, a proximal limb of jejunum (25 cm distal to the ligament of Treitz) is attached to the anterior abdominal wall in the left lateral quadrant with the endo-stitch. An additional 10 mm port in the right lower quadrant may be inserted to facilitate suturing of the jejunum

Figure 15 Pyloroplasty. (a) Pyloroplasty is performed using Harmonic shears. (b) Transverse closure of the pyloroplasty with endo-stitch technique.

Figure 16 Creation of a gastric tube. (a) The gastric tube is created by dividing the stomach starting at the distal lesser curve, preserving the right gastric vessels. (b) A 5 to 6 cm in diameter gastric tube is preferred. (c) Division of the gastric tube is from the esophagus.

to the anterior abdominal wall. A needle catheter (Compact Biosystems, Minneapolis, MN) is placed percutaneously into the peritoneal cavity. Under direct laparoscopic vision, the guide wire and catheter are directed into the loop of jejunum that has been tacked to the anterior abdominal wall. The entry site of the needle catheter J tube is tacked completely to the anterior abdominal wall for a distance of several centimeters.

The last step in the abdominal operation is the dissection of the phrenoesophageal membrane, which was delayed earlier to minimize the risk of losing the pneumoperitoneum into the mediastinum. The right and left crura are partially divided to permit easy passage of the gastric specimen and tube through the hiatus and to prevent later gastric outlet obstruction.

Next, a 4 to 6 cm horizontal neck incision is made [see Figure 18]. The cervical esophagus is exposed. Careful

dissection is performed inferiorly until the thoracic dissection plane is encountered. This is generally quite easy because the VATS dissection is continued well into the thoracic inlet. In addition, we leave the Penrose drain around the esophagus during the thoracic dissection and push the drain into the periesophageal plane at the thoracic inlet so that it is easily visualized during the neck dissection. This maneuver allows the surgeon to pull the Penrose drain out through the neck to facilitate the neck dissection. The esophagogastric specimen is pulled out of the neck incision and the cervical esophagus is divided high (1 to 2 cm below the cricopharyngeal muscle). The specimen is removed from the field. An anastomosis is performed between the cervical esophagus and gastric tube using a GIA stapler [see Figure 19]. Next, the surgeon returns to the laparoscopic view and gently pulls downward on the pyloroantral area to retrieve any excess gastric tube that may have been pulled up into the chest during the neck

Figure 17 Pulling up the gastric tube for cervical anastomosis.

anastomosis and mobilization. The laparoscopic pull is performed gently and only until the assistant at the neck observes the tube beginning to be pulled down at the level of the anastomosis. The esophagogastric cervical anastomosis is placed high in the neck, just below the level of the cricopharyngeus, to ensure adequate removal of any islands of Barrett and to ensure that any anastomotic leaks will be more likely to drain out via the neck. Three tacking sutures are placed: one between the left crus and stomach just anterior to the greater curve arcade; the second on the right side of the gastric tube just above the right gastric vessels to the right crus; and the third suture anteriorly between the stomach and the diaphragm.

TROUBLESHOOTING

The technical problems associated with VATS esophagectomy are similar to those associated with open thoracic esophagectomy, including thoracic duct injury, recurrent nerve palsy, bleeding from the intercostal vessels, and anastomotic leakage. These problems are best prevented by obtaining good visualization of the superior and posterior mediastinum, which can be achieved by using a 30° angled thoracoscope. The most common reason for conversion to thoracotomy is the presence of a locally advanced tumor that necessitates extensive dissection for safe mobilization away from adjacent mediastinal structures.

To date, comparison of the results of VATS esophagectomy with those of open esophagectomy has not shown VATS to yield a significant decrease in major complications,

especially postoperative respiratory insufficiency and cardiac arrhythmias. As a result, most centers still prefer the standard open transhiatal or transthoracic approaches to esophagectomy. VATS may also be used in the management of postoperative chylothorax. The thoracic duct can be ligated thoracoscopically, although it is sometimes difficult to identify and ligate the primary site of a postoperative lymphatic leak without reopening the thoracotomy.

VATS Pericardial Window

OPERATIVE TECHNIQUE

Some surgeons create a pericardial window by means of VATS as an alternative to taking the subxiphoid approach or the left anterior thoracotomy approach. A double-lumen endotracheal tube is inserted with the patient under general anesthesia, and the patient is rotated into the right lateral decubitus position. Three access sites are used, with the thoracoscope inserted at the seventh ICS in the posterior axillary line and the instruments introduced through two ports, one at the tip of the scapula and the other at the sixth ICS in the axillary line. The pericardium is retracted with a grasper forceps, and scissors are used to resect 8 to 10 cm² areas of pericardium both anterior and posterior to the phrenic nerve. If indicated, talc pleurodesis can be performed to control an associated pleural effusion. One or two chest tubes are then inserted through the port-site incisions.

TROUBLESHOOTING

When a pericardial effusion causes cardiac tamponade, a subxiphoid approach is preferable to VATS for creating a pericardial window because it is safer to perform in a hemodynamically unstable patient. A VATS pericardial window is also inadvisable in patients with constrictive physiology or with intrapericardial adhesions discovered at the time of operation. Conversion to an open procedure with formal pericardiectomy is advisable under these circumstances.

VATS Procedures for Mediastinal Masses

A 1998 multicenter trial aimed at defining the role of VATS in the management of mediastinal tumors suggested that VATS can be used safely to diagnose and resect most middle and posterior mediastinal masses, especially in view of the typically benign nature of these tumors.³⁴

VATS thymectomy has been used to treat myasthenia gravis and thymoma. To date, only anecdotal experience has been reported, and no studies examining long-term outcomes have been published. Although a VATS approach to myasthenia gravis may appear attractive at first, it is not the least invasive approach to the thymus. Transcervical thymectomy is a minimally invasive approach to the thymus that does not require a chest incision, does not violate the pleural space, and allows most patients to be discharged home the next day. There is still a degree of controversy as to whether complete thymic resection, including all ectopic thymic tissue, is necessary to obtain clinical remission in patients with myasthenia gravis. For patients with a thymic mass, we prefer a trans-sternal approach. It is imperative to maintain oncologic surgical principles; accordingly, en bloc resection is emphasized so that pleural seeding is avoided and the risk of incomplete

Figure 18 Neck incision.

resection is minimized. For patients with myasthenia gravis who do not have a thymoma, however, there is a need for prospective studies comparing VATS with other surgical approaches to thymectomy.

OPERATIVE TECHNIQUE

VATS has been used to resect masses in all of the mediastinal compartments. VATS resection is an ideal approach to posterior neurogenic tumors that do not extend into the neural foramen or the spinal canal. With the patient in the lateral decubitus position, the operating table is rotated

anteriorly so that the lung falls away from the paravertebral region. The port sites are placed anteriorly: the thoracoscope is inserted at the fifth ICS in the midaxillary line, a lung retractor is inserted at the sixth ICS in the anterior axillary line, and dissecting instruments are inserted at the second and fourth ICSs at the anterior axillary line. The mass is manipulated with a grasper to expose the posteriorly located pedicle, which is then dissected, ligated, and divided with the scissors, clip appliers, and electrocautery device.

For removal of anterior mediastinal masses, the port sites are placed in more posterior locations. The thoracoscope

Figure 19 Cervical anastomosis. (a) The cervical esophagus is divided high (1 to 2 cm below the cricopharyngeal muscle). (b) A side-to-side esophagogastric cervical anastomosis is performed using a gastrointestinal anastomosis (GIA) stapler. (c) Closure of the anastomosis by a 45 mm transverse anastomosis stapler.

is introduced at the fifth ICS at the midaxillary or posterior axillary line, and instruments are inserted through two ports, one at the second ICS at the midaxillary line and the other at the fifth or sixth ICS at the anterior axillary line. The mass is retracted with a grasper and dissected free with a combination of sharp and blunt dissection, clip appliers, and the electrocautery device. A similar technique is used to resect middle mediastinal masses, most of which are pericardial or bronchogenic cysts. The access sites should be chosen according to the location of the mass on the preoperative CT scan.

Generally, however, the triangulated site placement used for pulmonary wedge resections provides more suitable exposure than the site placement used for anterior or posterior mediastinal masses.

TROUBLESHOOTING

The placement of the thoracoports and the positioning of the operating team for the resection of posterior mediastinal tumors or for thoracic disectomy differ significantly from the usual practice in most other VATS procedures. In place

of the standard arrangement of trocars in an inverted triangle, the viewing port is placed in the posterior axillary line and the operating ports in the anterior axillary line. The thoracic surgeon and the neurosurgeon both stand on the anterior side of the patient, each viewing a monitor on the opposite side. In addition, a 30° scope is essential for visualizing the intervertebral disk space.

Removal of dumbbell neurogenic tumors can be accomplished thoracoscopically if immediately preceded by posterior surgical removal of the spinal component of the tumor via laminectomy and intervertebral foraminotomy. Preoperative MRI is crucial for defining the extent of the tumor within the spinal canal. Resection of posterior mediastinal tumors is sometimes associated with significant bleeding from intercostal or spinal arteries. If such bleeding occurs, there should be no hesitation in converting to a thoracotomy. Ideally, anterior mediastinal cysts should be resected in toto to prevent recurrence. However, if the cysts are firmly adherent to vital mediastinal structures, partial excision with cauterization of the endothelial lining may be safer.

VATS Management of Thoracic Trauma

The major contraindication to thoracoscopy in thoracic trauma is hemodynamic instability. For major life-threatening injuries involving the great vessels and the mediastinum, thoracotomy is required to obtain expeditious control of injured structures. However, hemodynamically stable patients with certain thoracic problems (e.g., diaphragmatic injury; slow, continued intrathoracic bleeding; persistent air leakage; and empyema) may be diagnosed and often treated by means of VATS.^{35,36}

In the assessment of a trauma patient with a potential diaphragmatic injury, it is important not to ignore the high incidence of associated intra-abdominal injury. If intra-abdominal injury has been ruled out and there is concern about the presence of a diaphragmatic tear, thoracoscopic assessment of the diaphragm is justified. Such assessment allows a more thorough evaluation of the entire diaphragm than the laparoscopic approach, which is limited by the liver on the right side. In the largest series published to date, 60 of 171 patients who underwent thoracoscopy for penetrating chest injuries had diaphragmatic injuries that necessitated repair.³⁷

When a patient has an ongoing intrathoracic problem (e.g., persistent bleeding or a large air leak 24 to 48 hours after a traumatic injury), VATS should be considered before a thoracotomy is done because most problems encountered at this time (e.g., chest wall bleeding and laceration of the lung parenchyma) can be managed endoscopically, without the need for a thoracotomy.

TROUBLESHOOTING

The main pitfall in thoracoscopic evaluation of the diaphragm is failure to assess the abdomen appropriately and consequent failure to recognize an occult intra-abdominal injury. When laparoscopy is performed in a patient with a diaphragmatic injury, insufflation of CO₂ may cause a tension pneumothorax to develop on the side of the diaphragmatic injury. Accordingly, whenever diaphragmatic injury is a

possibility, the chest should be included in the operative field to allow chest tube insertion if required. Because thoracoscopy does not require CO₂ insufflation, it is safer in such situations.

VATS Sympathectomy and Splanchnicectomy

Thoracic sympathectomy is known to be the most effective treatment for upper limb hyperhidrosis, and VATS is now an accepted approach to this operation. The main indication for splanchnicectomy is intractable abdominal pain from unresectable malignancies (e.g., pancreatic or gastric carcinoma) and chronic pancreatitis. The effects of celiac ganglion blocks are transient, and surgical manipulation of this area is usually very difficult because of the primary disease process, previous operations, or both. In the past, thoracotomy was generally considered too invasive an approach to splanchnic denervation in these patients. Currently, however, because of the less invasive nature of thoracoscopy and the quicker recovery time associated with it, thoracoscopic splanchnicectomy is an attractive therapeutic option.

OPERATIVE TECHNIQUE

Sympathectomy

VATS sympathectomy is performed with the patient under general anesthesia and a double-lumen tube in place. Several techniques have been described. Initially, the common practice was to use three port sites: one for the thoracoscope at the third ICS in the midaxillary line, one at the third ICS in the anterior axillary line, and one at the tip of the scapula. Currently, the procedure is most often performed with two incisions: one at the fifth ICS at the border of the pectoralis and one at the fourth ICS in the anterior axillary line. The pleura is incised and divided from T2 to T5, and the sympathetic chain is dissected free with scissors and excised. For complete control of upper limb hyperhidrosis, VATS must be done bilaterally.^{38,39}

A 1998 study reviewed the long-term results in 630 patients who had undergone thoracoscopic sympathectomy for hyperhidrosis (median follow-up 15 years).⁴⁰ Of these patients, 68% were fully satisfied and 26% were only partially satisfied but nevertheless would agree again to the operation. Hyperhidrosis was cured permanently in 93%. Compensatory sweating and gustatory sweating occurred in 67% and 47% of cases, respectively. Overall, patients were well satisfied with the results and considered the compensatory sweating less of a problem than the original hyperhidrosis.

Splanchnicectomy

The technical aspects of VATS splanchnicectomy are quite simple: sound knowledge of the splanchnic anatomy and a basic set of thoracoscopic instruments are all that is needed. Single-lung ventilation is required. Three thoracoports are placed. A silk stitch is placed in the central tendon of the diaphragm and pulled through the most anterior and inferior port to allow better visualization of the splanchnic nerves. The camera is also placed through this port. An endoscopic grasper and an endoscopic scissors with an electrocautery attachment are used to remove the nerve segment from T5 to T9. The greater and lesser splanchnic nerves are resected. The least splanchnic nerve is rarely visualized.

TROUBLESHOOTING

Care should be taken to identify the first and second ribs. Division of the sympathetic trunk at the level of the first rib causes Horner syndrome and does not reduce palmar hyperhidrosis. Division of the rami communicantes rather than the main sympathetic trunk reduces the incidence of undesirable side effects, especially compensatory hyperhidrosis of the trunk, but its overall success rate in controlling upper limb hyperhidrosis is lower. Abolition of only the T2 and T3 ganglia may control palmar hyperhidrosis without being as likely to result in unacceptable compensatory truncal sweating. Some have advocated limited T3 sympathectomy for primary hyperhidrosis to prevent compensatory sweating.⁴¹ Target areas for axillary sweating also include T4 and T5. In addition, an accessory sympathetic nerve fiber that runs lateral to the sympathetic chain (known as the nerve of Kuntz) should be sought and, if identified, divided. Compensatory hyperhidrosis of the inner thighs is a common complication. Neuralgia is frequent after VATS sympathectomy. Some authors advocate a 2-day postoperative course of dexamethasone to reduce the incidence of this problem.⁴²

Miscellaneous VATS Procedures

Several other procedures have been performed by VATS, including ligation of the thoracic duct⁴³ and resection of the adrenal gland.⁴⁴ For adrenal resection, three incisions are placed at the ninth or 10th ICS, extending from the anterior axillary line to the posterior axillary line. A fan retractor is inserted through a radial incision in the diaphragm and used to retract the perirenal fat. The adrenal gland is dissected free and removed, and the associated vessels are clipped or cauterized.

Cost Considerations

It is hard to estimate the cost-effectiveness of VATS procedures because the instrumentation, the types of procedures performed, and the surgical expertise with these operations are all still evolving. Initially, VATS procedures proved expensive for several reasons (e.g., the cost of purchasing video and endoscopic equipment, the cost of disposable instrumentation, and the need for long operating times as surgeons and nursing staff gained experience with the procedures). Soon after VATS was introduced, a study from the Mayo Clinic compared the cost of performing VATS

pulmonary wedge resections with that of the same operation done by thoracotomy.⁴⁵ The VATS approach was associated with substantially shorter hospital stays but also with increased operating room costs; hence, the use of VATS did not result in any significant overall savings. Since that study, however, as some VATS procedures (e.g., pulmonary wedge resection) have become standard operations and more reusable instrumentation has become available, the cost of VATS has undoubtedly decreased. Whether other, more complex VATS procedures (e.g., thoroscopic esophagectomy) are cost-effective remains to be determined.

Within this context, the Society of Thoracic Surgeons (STS) and the American Association for Thoracic Surgery (AATS) formed a joint committee to establish standards and guidelines for training and certification in VATS.⁴⁶ As a result of the educational efforts of this committee, many surgeons were trained within a short time, and VATS was quickly incorporated into thoracic surgical practice and residency training. The important considerations with respect to the training and practice of VATS have been well articulated.^{46,47}

VATS is not minor surgery: it is a minimally invasive, complex intrathoracic procedure that should be performed only by persons who are familiar with intrathoracic anatomy and pathology and are fully competent to manage complications and make intraoperative decisions in such a way as to ensure safe outcomes for thoracic surgical patients. The complications encountered during thoracoscopic operations are potentially immediately life-threatening, whereas those encountered during other endoscopic procedures usually are not. For that reason, VATS procedures should not be performed by anyone—surgeon or nonsurgeon—who lacks the training and experience to perform immediate thoracotomy and repair of intrathoracic injuries.

Conclusion

Since its reintroduction into clinical practice in the early 1990s, VATS has been investigated in a scholarly and academically rigorous manner. It represents a paradigm for the evaluation of surgical innovation, leading to safe and effective application in patients. This chapter describes the most common video-assisted thoracic procedures performed in the current practice of thoracic surgery.

11 MEDIASTINAL PROCEDURES

Joseph B. Shrager, MD, FACS, and Vivek Patel, MBBS

Procedures for Lesions of the Anterior Mediastinum

More than half of all mediastinal masses arise from the anterior compartment. Most primary malignancies of the mediastinum also develop in the anterior mediastinum. Because of the narrowness of the space that makes up the thoracic inlet, as well as the presence of the trachea and esophagus traversing this region, anterior mediastinal masses become symptomatic earlier than their counterparts in other anatomic spaces of the mediastinum. Whereas adults with masses of the middle or posterior mediastinum usually report no significant symptoms, more than 50% of patients with anterior mediastinal masses present with chest pain, fever, cough, dyspnea, dysphagia, or vascular obstruction. Thymic neoplasms and lymphoma, the two most common masses in the anterior mediastinum, may have systemic manifestations (e.g., weakness associated with myasthenia gravis [MG] or symptoms associated with International Working Formulation [IWF] group B lymphoma).

In what follows, we focus on surgical approaches to the diagnosis and treatment of the more common neoplasms of the anterior mediastinum, including thymic tumors, lymphomas, and germ cell tumors. Embryologic anomalies and neoplasms arising from normal structures in this region broaden the differential diagnosis [see Table 1]. Finally, we address thymectomy for MG, a procedure that is frequently performed even in the absence of neoplastic disease.

PREOPERATIVE EVALUATION

In a patient with an anterior mediastinal mass, it is frequently possible to make a strong provisional diagnosis of the tumor type on the basis of clinical evaluation and diagnostic imaging.¹ As noted (see above), the presence of systemic manifestations may be helpful. Physical examination must include examination of peripheral lymph node groups and testes. Computed tomography (CT) yields valuable information about the anatomic location of the tumor, its characteristics (i.e., fatty, solid, or cystic), and its degree of invasiveness (if any) [see Figure 1]. Occasionally, magnetic resonance imaging (MRI) provides useful additional information about the obliteration of normal tissue planes. Positron emission tomography (PET) generally demonstrates strong fluorodeoxyglucose (FDG) uptake in lymphoma; thus, PET and CT may be useful in guiding sites for biopsy in that disease. Several small trials have been conducted evaluating the utility of PET in the evaluation of thymoma.² Uptake of FDG appears to be greater in thymoma than in thymic hyperplasia, and thymic carcinomas appear to have the highest FDG uptake. The reproducibility and thus diagnostic utility of this finding, though, have yet to be clearly elucidated.

Lymphoma is the most likely diagnosis in persons younger than 40 years, and the presence of IWF group B symptoms further raises the level of suspicion. The presence of palpable

remote adenopathy or an elevated serum lactate dehydrogenase level is also suggestive.³ When peripheral nodes are palpable, the diagnosis may be most easily obtained by excising one of them. Patients with suspected lymphoma who have an isolated anterior mediastinal mass should undergo core-needle biopsy or a Chamberlain procedure (anterior mediastinotomy), depending on the pathologists' level of comfort with classifying lymphoma on the basis of small specimens at one's institution. Resection of lymphoma is not indicated; it may be avoided by performing a diagnostic biopsy whenever lymphoma is suspected.

Unlike lymphomas, thymic neoplasms are uncommon before the fourth decade of life. Thymoma [see Figure 1a] may be associated with any of several paraneoplastic syndromes. MG occurs in conjunction with a pathologic condition of the thymus—either thymoma or thymic hyperplasia—in 80 to 90% of cases. Thymoma may also be associated with pure red cell aplasia, agammaglobulinemia, systemic lupus erythematosus, and various autoimmune disorders. The presence of any of these associated syndromes essentially clinches the diagnosis of thymoma. Autoantibodies to the acetylcholine receptor (anti-AChR antibodies) should be measured: their presence is diagnostic of MG, and they are found in nearly 60% of patients who have thymoma without neurologic symptoms.⁴ Once the diagnosis of thymoma has been made, the goal is to proceed to direct resection without preliminary biopsy; these tumors have a predilection for local recurrence once the capsule has been violated.

The majority of germ cell tumors, whether malignant or benign, are diagnosed in the second or third decade of life. Benign teratomas are usually well encapsulated, with frequent recapitulation of one or more tissue elements seen on radiography.⁵ The appearance of the lesions on CT is often diagnostic [see Figure 1b]. Surgical extirpation is the mainstay of treatment for these mature germ cell tumors, and biopsy is not indicated. Malignant germ cell tumors, on the other hand, are treated with primary chemotherapy, radiotherapy, or both; when suspected, these patients should undergo biopsy rather than being taken directly to resection. Characteristic serum tumor markers, including β -human chorionic gonadotropin (β -hCG) and α -fetoprotein (AFP), are elaborated by most malignant germ cell neoplasms but are not found in benign germ cell tumors.⁶ Elevation of the AFP level beyond 500 ng/mL is considered diagnostic of a nonseminomatous component in a malignant germ cell tumor and is usually associated with a concomitant increase in serum β -hCG levels.⁷ In the absence of any marked elevation in the AFP or β -hCG level, percutaneous needle biopsy usually suffices to establish the diagnosis.

OPERATIVE PLANNING

Biopsy versus Resection

Clearly, the decision whether to perform a biopsy of an anterior mediastinal mass is not a simple one. Routine biopsy

Dilation of superior vena cava (with anomalous pulmonary venous return)
Persistent left superior vena cava

should be avoided, not only because of the cost and the unnecessary morbidity but also because of the risk that biopsy may spread thymoma. The choice to proceed with biopsy should be made according to which tumor type is believed to be most likely on the basis of the diagnostic workup.

Well-encapsulated lesions that are believed not to represent lymphoma are resected, without a preceding biopsy, for both diagnosis and treatment. Neoplasms that commonly fall into this category include noninvasive thymomas, mature teratomas, mesenchymal tumors, and, occasionally, benign cysts. Most patients with MG should be offered thymectomy whether they have a thymic mass or not.

When lymphoma is suspected, biopsy is required. The technique employed should be minimally invasive while still permitting the acquisition of a sufficient tissue sample. CT-guided core-needle biopsy may be attempted, but, frequently, this technique does not provide enough tissue for the analyses required to classify the tumor.^{8,9} Thus, the Chamberlain procedure (anterior mediastinotomy) is recommended in these situations.

For locally invasive or frankly unresectable anterior mediastinal masses other than those felt likely to represent

Figure 1 (a) Computed tomography (CT) scan shows a well-encapsulated anterior mediastinal mass—a thymoma. (b) CT scan shows a benign teratoma of the anterior mediastinum; calcification and varying tissue densities may be seen.

lymphoma, biopsy is also preferable to immediate attempt at resection. Such lesions may represent aggressive thymomas that may benefit from neoadjuvant treatment, malignant germ cell tumors, or other rare disease processes. Once the decision has been made to proceed with biopsy rather than resection, selection of a biopsy approach is based on anatomic considerations and patient factors.

BIOPSY OF ANTERIOR MEDIASTINAL MASS

Chamberlain Approach

Anterior parasternal mediastinotomy (the Chamberlain procedure) is favored by most surgeons for biopsy of lesions in the anterior mediastinum and the aortopulmonary window. It is usually done under general anesthesia, although local anesthesia may be used instead, and it does not require single-lung ventilation. This operation affords good exposure and allows generous biopsy specimens to be taken, and it can be performed as an outpatient procedure.

Operative technique *Step 1: initial incision* A 5 cm transverse incision is made over the second costal cartilage on the side to be operated on (the second cartilage is identified by its continuity with the sternal angle). The pectoralis major is separated in a direction parallel to the direction of its fibers,

Figure 2 Biopsy of anterior mediastinal mass: Chamberlain approach. Depicted are incision and subperiosteal resection of the second costal cartilage.

and the cartilage is resected in a subperiosteal plane [see Figure 2]. Leaving perichondrium behind facilitates postoperative regrowth of the cartilage.

Step 2: dissection and exposure The posterior perichondrium is incised, and the parietal pleura is bluntly dissected laterally with a peanut sponge; this affords entry into the mediastinal fat and direct access to the tumor mass. Almost invariably, the internal mammary vessels can be mobilized medially and preserved, but, if necessary, they may be ligated to improve exposure.

Step 3: biopsy A generous wedge-shaped portion of the mass is excised with a scalpel. Frozen-section examination is then performed to confirm that diagnostic tissue has been obtained. It is important to remember to request that flow cytometry be performed on the specimen.

Step 4: closure The posterior perichondrium is reapproximated, followed by the pectoralis major, the subcutaneous fat, and the skin.

Troubleshooting If the pleura was entered, a red rubber catheter is used to evacuate the pleural space as the lung is inflated with a large positive pressure breath, and the catheter is withdrawn through the layers of closure. A small postoperative pneumothorax is almost always attributable to residual air rather than to an ongoing air leak.

Sometimes the tumors are fairly vascular and bleed moderately after biopsy is performed. This bleeding can always

be controlled with electrocauterization. We often leave an absorbable hemostatic agent in place as well.

Transcervical Approach

As an alternative to the Chamberlain procedure, a mass of the anterior mediastinum may be approached for biopsy through a cervical incision, exactly as in a transcervical thymectomy [see Resection of Anterior Mediastinal Mass, Transcervical Approach, below]. The use of a Cooper thymectomy retractor (Pilling Company, Fort Washington, Pennsylvania), which elevates the sternum, affords excellent exposure of the anterior mediastinum and sometimes allows direct examination to ascertain the invasiveness of an otherwise uncertain mass. In most cases, general anesthesia is required, but transcervical biopsy can be performed as an outpatient procedure. We have used this technique occasionally and have achieved results comparable to those of anterior mediastinotomy.¹⁰ Proper performance of this procedure does, however, require a level of experience with the technique that is not widely available.

Video-Assisted Thoracic Surgery

Video-assisted thoracic surgery (VATS) has been applied to diagnostic biopsy of anterior mediastinal masses, but VATS biopsy procedures are not widely employed for this purpose. The necessity of single-lung ventilation adds a level of complexity to the procedure beyond what is required for the

Chamberlain procedure or the transcervical approach. Furthermore, intercostal incisions are frequently more painful than transcervical incisions or the incision for an anterior mediastinotomy. VATS does have certain advantages that may be of value in individual cases, such as the capacity to provide simultaneous access to other compartments of the mediastinum and the ability to evaluate the pleural space for evidence of tumor dissemination. Robot-assisted thoracoscopic procedures for anterior mediastinal masses have also been described,¹¹ but their availability does not eliminate the major objection to transpleural approaches to mediastinal masses—namely, the possibility of spreading a disease that had been contained within the mediastinum into the pleural space.

RESECTION OF ANTERIOR MEDIASTINAL MASS

Operative Planning

The most frequent indications for resection (as opposed to biopsy) of an anterior mediastinal mass are (1) thymoma and (2) thymectomy for MG. The principles underlying thymoma resection can be applied to resection of other, rarer anterior mediastinal masses such as thymic carcinoma, thymolipoma, and germ cell tumors. The first successful resection of a thymic mass for MG was described in 1939.¹² Since the introduction of transcervical thymectomy (TCT), there has been ongoing debate regarding the optimal method for thymectomy in patients with nonthymomatous MG. There is little debate, however, regarding the optimal approach to resection of anterior mediastinal malignancies.

For all primary invasive masses of the anterior mediastinum—including invasive thymomas, malignant germ cell tumors (after systemic treatment), thymic carcinomas, and other, less common malignancies—the most important prognostic factor is complete resection. Accordingly, the operative approach must be selected with an eye to providing optimal exposure. There is little doubt that a full median sternotomy is ideal in this regard. However, a less than full sternotomy is a reasonable choice for small (< 3 cm) noninvasive thymomas or other noninvasive mediastinal tumors (e.g., mature teratomas), particularly when the diagnosis of thymoma is in doubt before operation. In such situations, we usually begin with TCT,^{13,14} but we do not hesitate to convert to a sternotomy if unexpected invasion is identified. Some surgeons have employed a partial upper sternotomy in these settings; however, this approach limits exposure, and we do not believe that it actually reduces morbidity in comparison with a full sternotomy. Video thoracoscopic (VATS) and even robotic thymectomy have now been described by a number of groups employing several technical variations and with apparently good results. These approaches have, like TCT, been applied generally to patients with MG without thymoma or those with small, noninvasive thymomas. Studies with longer follow-up reporting myasthenia remission rates and thymoma cure rates will be required before these VATS and robotic approaches can be considered to have a proven role in the management of these diseases.

En bloc resection of malignancies is mandatory, and resection of adjacent serosal membranes (including pleura or pericardium) is required if there is any suggestion of attachment during the operation. Resection of adjacent lung parenchyma

is not uncommon, and resection of the great vessels has been performed with both technical success and good long-term survival. All great vessels resected must be reconstructed, with the exception of the innominate vein, which may be ligated with little deleterious effect. Every effort should be made to preserve the phrenic nerves: damage to even one of these nerves can be disastrous in an already weakened myasthenia patient. In a patient with a malignancy, however, one phrenic nerve may be sacrificed if tumor invasion necessitates this step, provided that the patient's preoperative respiratory status is acceptable and curative resection is likely.

In cases of thymectomy for advanced MG, every effort must be made to optimize the patient's condition preoperatively. To this end, a multidisciplinary approach that includes a neurologist and, possibly, a pulmonologist is necessary. If the disease does not stabilize with medication (e.g., pyridostigmine, low-dose steroids, or intravenous γ -globulin), preoperative plasmapheresis may be required. Patients with moderate or greater generalized weakness despite optimization of medication should certainly undergo plasmapheresis. The question of which MG patients should be offered thymectomy is, at best, difficult to answer. Most studies have found the impact of thymectomy to be greater if it is performed in patients with less severe and shorter-duration disease. Accordingly, our practice is to offer TCT sooner in the course of the disease rather than later; however, we will perform the procedure at any stage, from ocular-only disease to severe, generalized weakness. Because TCT is associated with minimal morbidity, requires only a small incision, and can generally be done as an outpatient procedure, it is a very attractive option for patients with milder disease. At the same time, it is also more easily tolerated by patients with severe disease than is a median sternotomy.

An approach to thymectomy for MG that is favored by a few surgeons is so-called maximal transsternal-transcervical thymic resection, which combines a median sternotomy with an additional neck incision to provide wide access to all areas where thymic tissue has been identified. The rationale for such extensive exposure is the observation that thymic tissue may reside in several extrathymic locations. Proponents of the maximal approach argue that if thymectomy for MG is to provide optimal benefit, it should include removal of all of this extraglandular thymic tissue. This approach has never been compared to TCT in a randomized trial, but, in our view, most of the available data suggest that remission rates after maximal transsternal-transcervical thymic resection are not remarkably different from those after TCT, which is much less invasive. Because we do not personally perform the maximally invasive procedure, we do not describe it in this chapter.

Median Sternotomy Approach

As noted (see above), the standard approach to masses of the anterior mediastinum is via a median sternotomy. Resection of a thymoma of the anterior mediastinum is performed as follows.

Operative technique *Step 1: initial incision and exposure*

The patient is placed in the supine position and intubated with a double-lumen endotracheal tube. The skin incision

typically extends from 2 cm below the jugular notch to the xiphisternal junction; however, depending on the extent of the expected pathologic condition, the incision may be shortened further and the full sternum divided by reaching beneath skin flaps. Finger dissection is performed beneath the sternum to rule out tumor invasion into the posterior sternal table. If the posterior sternal table is clear, the sternum is divided, hemostasis is achieved, and the edges are separated with a sternal retractor.

Step 2: determination of resectability The anterior mediastinum is inspected, the mass is visually identified, and an initial assessment of resectability is undertaken.

Step 3: mobilization of inferior poles of thymus Dissection of the thymus begins at the caudad aspect, with the inferior poles and surrounding mediastinal fat mobilized first from the underlying pericardium and diaphragm by electrocautery dissection. It is difficult to determine by visual means precisely where thymic tissue merges into simple mediastinal fat; accordingly, to ensure complete resection of the thymus, all fatty tissue between the phrenic nerves and down to the level of the diaphragm is removed with the specimen. The mediastinal pleura, to which this fatty and thymic tissue tends to be adherent, is also taken with the specimen [see Figure 3]. This is done by first opening the mediastinal pleura along the entire length of the chest, approximately 1 cm posterior to the sternum.

Step 4: continuation of dissection cephalad From within the pleural space, the phrenic nerves are identified and followed along their entire path up to the point where they course beneath the innominate vein. Sharp dissection is carried close to the nerves, dividing the mediastinal pleura again along this more posterior line, to secure an adequate tumor margin and ensure removal of all thymic tissue that is progressively mobilized medially. It is advisable to clip small vessels near the nerves before dividing them so as to prevent irritating bleeding, which can be difficult to control without compromising the nerve.

Figure 3 Resection of anterior mediastinal mass: median sternotomy approach. Intraoperative photograph shows dissection of the right inferior thymic pole and associated mediastinal fat.

The small arteries supplying the thymus, which are most often not even clearly seen arising laterally via branches from the internal mammary vessels, are coagulated or ligated and divided as they are encountered. Care must be taken to stay away from the phrenic nerves while controlling the arterial blood supply.

Step 5: mobilization of superior poles of thymus Dissection is then continued in the neck, where the two cervical extensions are isolated by means of gentle traction and blunt dissection and followed until they trail off into the thyrothymic ligament. This ligament is clamped, divided, and ligated superiorly at a point where only a small blood vessel is present and no visible glandular tissue remains.

Step 6: dissection of thymus from innominate vein The cervical poles are followed down over the innominate vein. Sharp dissection is continued onto the surface of the vein, and the two to five veins draining the gland into the innominate vein are ligated and divided [see Figure 4].

Step 7: removal of specimen Once the body of the thymus has been freed from the innominate vein, the H-shaped gland and the associated mass are removed [see Figure 5]. If the

Figure 4 Resection of anterior mediastinal mass: median sternotomy approach. View from feet shows the thymus and tumor mobilized off the innominate vein. The entire right thymus (both the upper and the lower pole) has been fully mobilized.

Figure 5 Resection of anterior mediastinal mass: median sternotomy approach. Shown is the resected thymoma specimen.

clean plane between the mass and the underlying pericardium—a plane normally composed of fine, filmy adhesions—is at all compromised, one should not hesitate to resect a portion of the pericardium en bloc with the specimen, with care taken to maintain a gross margin of at least 2 cm at all times.

Step 8: closure Two pleural drains that traverse the mediastinum and reach the apex of each hemithorax are placed, and the sternum and the soft tissues are reapproximated in layers.

Troubleshooting If invasion of great vessels is considered a possibility before the start of the operation, the groin should be prepared and draped into the field to provide access for cardiopulmonary bypass if needed. Giant anterior mediastinal masses may necessitate extension of a partial median sternotomy incision into an ipsilateral intercostal space (usually the fourth space). Such extension may be achieved by making an ipsilateral incision in the neck along the anterior border of the sternocleidomastoid muscle and making a submammary skin incision continuous with the incision over the sternum (a hemiclamshell incision) [see Figure 6].

Transcervical Approach

Although the transcervical approach to thymic resection was the first one used in the early 1900s, it fell into disuse during the middle of the 20th century, when the median sternotomy approach became feasible. During the past 20 years, however, there has been a resurgence of interest in TCT. Today, TCT is used primarily for thymectomy in the setting of MG, although, as noted (see above), a transcervical approach can be useful for biopsy or resection of other anterior mediastinal processes as well. Proponents of TCT have published data establishing that complete remission rates from MG after so-called extended TCT using the sternum-lifting Cooper retractor¹⁵ are very similar to remission rates after the more invasive approaches.^{14,16,17} Because TCT is an outpatient procedure, hospital stay and operative recovery are certainly dramatically shorter than after thymectomy by sternotomy.

Figure 6 Resection of anterior mediastinal mass: median sternotomy approach. Hemiclamshell incision provides exposure to masses located at the thoracic apex.

TCT should be employed very cautiously in cases in which a neoplasm is suspected or proved on the basis of preoperative studies or is identified during the course of intraoperative exploration. Because thymoma is often an indolent tumor, with recurrence developing many years after resection, long-term follow-up studies are required before TCT can be firmly recommended for treatment of even small thymomas. On the other hand, it is likely that surgeons who have extensive experience with TCT can safely resect small (< 3 cm) thymomas via this approach without risking tumor spillage or incomplete resection.

Operative technique *Step 1: initial incision and exposure*

The patient is placed on the operating table in the supine position, with the head supported by a foam doughnut and an inflatable bag placed horizontally beneath the scapulae. The bag is inflated until the cervical spine is maximally extended. It is important that the top of the patient's head be all the way up to the edge of the table so that the surgeon can easily reach all areas of the mediastinum from a seated position at the head.

A 5 to 6 cm curvilinear incision is made about 2 cm superior to the jugular notch and extending about 1 cm above each clavicular head [see Figure 7]. Electrocautery dissection is continued through the platysma, and subplatysmal flaps are elevated. The strap muscles are separated in the midline, and the interclavicular ligament is divided. Separating a small portion of the attachment of each sternocleidomastoid muscle from the corresponding clavicular head allows the sternum to be elevated somewhat higher, thereby improving exposure.

Step 2: mobilization of superior poles of thymus The superior poles of the thymus are located (usually on the left side first) by means of gentle blunt dissection beneath the strap muscles. After one pole is identified, it is divided between ties at its superior extent. Its medial edge is then followed down to where it meets the medial edge of the opposite superior pole, and this opposite pole can then be similarly traced upward

Figure 7 Resection of anterior mediastinal mass: transcervical approach. Shown is the location of the skin incision for transcervical thymectomy in relation to the sternal notch and the heads of the clavicles.

into the neck, ligated, and divided. A very important part of the procedure is the placement of 0 silk ligatures around an area containing strong tissue within each superior pole. These ligatures are left long and clamped. The surgeon or an assistant places traction on them during the remaining course of the dissection to manipulate and progressively mobilize the gland [see Figure 8].

Step 3: continuation of dissection downward into superior mediastinum As traction is being placed on the upper poles, sharp and blunt dissection, staying outside the well-defined capsule of the gland, is extended downward into the superior mediastinum to the level of the innominate vein. The procedure becomes much more difficult if the capsule is violated.

Step 4: elevation of sternum Finger dissection is performed in the substernal plane, and the arm of a Cooper thymectomy retractor is placed into the retromanubrial space to elevate the sternum. The retracting arm is placed under upward tension as the inflatable bag beneath the shoulders is deflated. This step leaves most patients actually hanging from the retractor, thereby opening up a sizable space that allows good visualization and ready passage of dissecting instruments into the anterior mediastinum. Army-Navy retractors are placed in each of the two upper corners of the incision, and their distal ends are tied to the siderails of the table with Penrose drains to provide countertraction and to hold the skin incision open.

Step 5: dissection of venous tributaries to innominate vein With the superior poles gently pulled upward by an assistant (and at times looped over the Cooper retractor), the inferior surface of the gland is dissected until the innominate vein is encountered. The venous tributaries draining the thymus into the innominate vein are isolated sharply, ligated with fine silk sutures, and divided.

Figure 8 Resection of anterior mediastinal mass: transcervical approach. A Cooper thymectomy retractor is placed beneath the sternum, and retraction on the upper poles of the thymus is maintained with silk sutures.

Step 6: dissection of posterior aspect of thymus Once the thymus is freed from the innominate vein, dissection of the posterior aspect of the gland must be continued directly on the surface of the pericardium. This posterior dissection is carried as far down as possible, primarily in a blunt fashion. Most of the time, the surgeon holds one ring clamp containing a sponge dissector in each hand while an assistant holds the upper poles. Occasionally, the surgeon holds the sutures attached to the upper poles in one hand while employing the sponge dissector in the other hand.

Step 7: removal of specimen When the posterior dissection has been extended as far as possible toward the diaphragm, further mobilization of the thymus is typically accomplished by working the glandular tissue laterally, first off the pleura on one side, then off the sternum anteriorly, and finally off the pleura on the opposite side. In this way, the entire gland is ultimately removed between the phrenic nerves and down to the diaphragm. During this final mobilization, the surgeon periodically asks to have ventilation held temporarily so that the pleura can fall back and thus permit improved visualization. Small feeding vessels from the mammary are doubly clipped and divided as they are encountered.

Often the final stages of blunt dissection may be facilitated by placing a ring clamp on the body of the gland to allow slightly more vigorous retraction than can be achieved by using the upper poles alone. If any suspicious residual tissue is seen in the mediastinum at this point, it can be removed piecemeal; however, this is an unusual occurrence.

Step 8: closure After inspection of the surgical field for hemostasis, the strap muscles and the platysma are closed over a red rubber catheter, to which suction may be applied. The catheter is subsequently removed, and the skin is closed.

Troubleshooting In the course of preoperative evaluation before TCT, it is important to be sure that the patient is able to extend the neck to a reasonable degree. TCT is simplest in young persons who are capable of good extension; it can be difficult or impossible in persons with cervical spine disease that hinders extension.

During the procedure itself, it is important that the branches of the innominate vein be tied rather than clipped; the space anterior to the vein becomes the avenue through which dissecting instruments are passed into and out of the mediastinum, and these instruments often rub against the vein fairly vigorously.

When working laterally, one must take care not to injure the phrenic nerves, and one certainly should not use the electrocautery while working at the lateral extremes of the dissection. If the pleural space is entered while one is working laterally, a red rubber catheter [see Operative Technique, Step 8, *above*] is advanced well into that pleural space, and suction in the form of several large positive-pressure breaths is applied before the catheter is removed.

If a thymoma is encountered during TCT, continuation via this approach may be considered. In our view, most noninvasive thymic lesions less than 3 cm in diameter can be safely and completely resected via the transcervical approach. In addition, it generally is not difficult to resect a portion of the anterior pericardium as well if a tumor or the thymus is adherent to it. However, because the evidence currently available does not conclusively establish that TCT is equivalent to resection via sternotomy for thymoma, some surgeons prefer to convert to a sternotomy if a suspicious mass is discovered during transcervical exploration. Certainly, if any difficulty is encountered that might lead to an incomplete thymectomy or incomplete removal of a thymoma, the incision should be extended.

Approximately 90% of patients are able to go home on the same day as their procedure. The most common cause for hospital admission is a pneumothorax that must be monitored or drained. Occasionally, a seroma develops at the site of the incision, but it almost always resolves either spontaneously or after a single percutaneous drainage procedure in the office.

VATS/Robotic Thymectomy

Although we do not have personal experience with VATS or robotic thymectomy and will therefore not include a discussion on its technique, an increasing number of published reports suggest that these are safe and effective alternatives to transsternal and transcervical approaches. Since the first sporadic case reports of VATS thymectomy in the early 1990s, the popularity of this procedure has increased, likely because of the increased availability of VATS instrumentation, surgeon familiarity with VATS techniques, and

increased awareness of minimally invasive strategies. Proponents of VATS thymectomy cite decreased postoperative pain, decreased length of stay, improved cosmesis, and less morbidity than sternotomy as reasons in support of VATS thymectomy. Most case series report complete stable remission rates from MG^{18,19} comparable to transsternal and transcervical approaches. The data in this area, however, are not nearly as mature as those in support of TCT or sternotomy for thymectomy.

The drawbacks of VATS thymectomy depend on the particular technical approach that is chosen, which include unilateral, bilateral, and substernal approaches. As with any minimally invasive technique, detractors have pointed out that there may be an inability to provide complete clearance of all thymic tissue. It has been suggested that a unilateral VATS approach may provide inadequate access to the portion of the gland approaching the contralateral phrenic nerve. Aside from the question of the completeness of thymectomy, any transthoracic, minimally invasive approach may create a small risk of transpleural seeding in patients with thymoma. Given that “drop metastasis” to the pleural surfaces is the typical mode of spread of thymoma, there is substantial concern that a transpleural, thoracoscopic approach may facilitate this mode of spread.

Procedures for Lesions of the Middle Mediastinum

The majority of masses found in the middle mediastinum in adults are malignant, representing either lymphoma or lymph node metastases from primary lung carcinoma. Accordingly, the procedures performed in this anatomic area primarily involve biopsy for staging or diagnosis rather than curative or palliative resection. On infrequent occasions, however, benign or primary malignant lesions of the middle mediastinum occur for which resection is appropriate. In what follows, we briefly discuss resection of such lesions; for the most part, the principles are the same as those underlying resection of masses in the posterior mediastinum [see Procedures for Lesions of the Posterior Mediastinum, *below*].

Of particular surgical interest in the middle mediastinum are benign cysts, which may arise from the pleura, the pericardium, the airways, or the esophagus. Bronchogenic cysts, which typically develop in proximity to the carina, are probably the middle mediastinal cysts most commonly encountered in clinical practice, with pericardial cysts running a close second. On rare occasions, ectopic remnants from cervical structures (e.g., the parathyroid and thyroid glands) are encountered in this compartment.²⁰

PREOPERATIVE EVALUATION

CT generally provides an accurate preoperative diagnosis of a benign middle mediastinal cyst, as well as information regarding abutment of adjacent structures, the consistency of the mass, and potential invasiveness. MRI may be helpful if there is concern that a cyst might actually represent an aberrant vascular structure or an aneurysm, if the simple nature of the cyst is in doubt, or if clearer delineation of suspected invasion of surrounding structures is required. Radionuclide scans (e.g., with technetium-99m or radioactive iodine) may

be useful if the differential diagnosis includes a parathyroid or thyroid mass. Cystic structures adjacent to the airways and the esophagus are evaluated by means of bronchoscopy, esophagoscopy, barium esophagography, or some combination of these imaging modalities to rule out communication with the lumina.

OPERATIVE PLANNING

Middle mediastinal cysts that are symptomatic should be treated surgically. However, simple cysts of the middle mediastinum that are asymptomatic and meet all radiographic criteria for benignity may be followed. This conservative approach is often more appropriate for asymptomatic middle mediastinal cysts than for asymptomatic posterior mediastinal cysts in that complete cyst resection (at least for bronchogenic cysts) tends to be more complex in the middle mediastinum than in the posterior mediastinum, given the closer proximity to vital structures and the deeper placement within soft tissue. Complete resection of pericardial cysts, on the other hand, typically is easily accomplished by means of VATS; therefore, such cysts are probably best resected when discovered, even if they are asymptomatic. VATS resection of subcarinal bronchogenic cysts is feasible and has been described in published reports.²¹ It is our experience, however, that larger and more chronic cysts in this location may be difficult to remove completely by a VATS approach.

Thus, for a symptomatic, large, or chronic subcarinal bronchogenic cyst (a not uncommon occurrence), one is left to choose between (1) thoracotomy for complete resection and (2) some other approach for incomplete resection. Because this area is easily accessible by means of mediastinoscopy, and because we believe that mediastinoscopy is simpler and causes less morbidity than VATS, we prefer partial resection via mediastinoscopy as the initial approach to these lesions.²² If cysts treated in this manner recur with associated symptoms, one can always perform thoracotomy for complete resection at that time, and little will have been lost in the meantime.

MEDIASTINOSCOPIC PARTIAL RESECTION OF SUBCARINAL BRONCHOGENIC CYST

Operative Technique

Step 1: mediastinoscopy and pretracheal dissection

A standard cervical mediastinoscopy is performed, with dissection in the pretracheal plane down to the level of the carina.

Step 2: freeing of cyst from surrounding tissues With the cyst wall kept intact, as much of the wall as can safely be exposed is visualized by bluntly dissecting it away from the undersurface of the carina and the mainstem bronchi. Next, the mass is dissected away from the soft tissues anterior and posterior to it; obviously, this must be done with caution, given that the right main pulmonary artery and the esophagus are located nearby (anteriorly and posteriorly, respectively).

Step 3: aspiration of cyst contents and excision of exposed cyst wall The contents of the cyst are aspirated for cytologic and microbiologic examination, and the exposed

portion of cyst wall is excised. Typically, approximately 50% of the cyst wall can be removed in this fashion. Some of the remaining cyst wall may be cauterized; this too must be done with caution, given the proximity of the adjacent vital structures.

Procedures for Lesions of the Posterior Mediastinum

The majority of posterior mediastinal masses occurring in adults are benign. These lesions may be usefully classified according to their radiologic appearance—that is, as either cystic or solid. Cystic masses in this region typically are bronchogenic cysts or esophageal duplication cysts, whereas solid masses most frequently are benign neurogenic tumors (e.g., schwannomas, neurofibromas, or ganglioneuromas). Esophageal leiomyomas (benign intramuscular tumors within the esophageal wall) are often grouped with these posterior mediastinal lesions and are managed in a similar fashion. In many cases, posterior mediastinal masses come to light as asymptomatic radiographic abnormalities; however, they may also be associated with signs of infection (in the case of infected cysts), dysphagia, chest pain, or respiratory complaints. At present, because of the growing availability of less morbid, minimally invasive approaches to posterior mediastinal masses, most authors recommend resection even when the lesion is asymptomatic. Although this recommendation remains somewhat controversial, we agree with it.

OPERATIVE PLANNING

VATS versus Thoracotomy

Resection of posterior mediastinal masses may be accomplished by means of either VATS or thoracotomy. The procedure is essentially the same with either approach, and the goal is complete resection. With some exceptions, VATS is considered preferable to thoracotomy in this setting; generally, VATS results in less postoperative pain and quicker functional recovery.^{23,24} Some surgeons argue that a VATS approach may be more likely to leave a patient with microscopic residual disease. In our experience and that of others, however, recurrences of these lesions are very rare after VATS excision.^{25,26} Given the low recurrence rate and the fact that these masses are almost always benign, we believe that the risk-benefit ratio favors VATS in most cases.

There are, however, several circumstances in which thoracotomy is indicated from the outset [see Table 2]. A suggestion of malignancy (in particular, invasion of surrounding structures) on preoperative radiography mandates exploration and resection by thoracotomy; in this situation, the potential consequences of positive margins justify the more aggressive approach. The presence of active infection within a cyst is a relative indication for thoracotomy in that it can cause disruption of normal tissue planes and thereby render VATS dissection more hazardous. Masses larger than approximately 6 cm also call for an open approach: such lesions are typically more difficult to mobilize safely from underlying structures than smaller lesions are, they are more likely to be malignant, and their removal between the ribs is likely to necessitate rib spreading, which may negate some of the benefit of true VATS.

Table 2 Indications for Planned Thoracotomy Approach to Middle or Posterior Mediastinal Mass

Suggestion of malignancy on preoperative radiography
Presence of inflammation or infection, blurring tissue planes
Large mass (> 5–6 cm)
Esophageal duplication cyst believed to communicate with esophageal lumen on the basis of preoperative computed tomography, barium esophagography, or esophagoscopy
Esophageal lesions without evidence of overlying normal esophageal mucosa on preoperative esophagoscopy or endoscopic ultrasonography
Previous ipsilateral thoracotomy with adhesions
Tumor located at apex of the chest, which may necessitate thoracosternotomy

When a cyst is arising from or abutting the esophagus, the possibility of a communication between the cyst and the esophageal lumen should be investigated preoperatively. Such a communication may be suggested on CT scans by the presence of an air-fluid level. To rule out this phenomenon, we perform barium esophagography during the preoperative workup, followed by intraoperative esophagoscopy at the commencement of the operation. If a communication is identified or cannot be ruled out, thoracotomy is performed. After excision of an esophageal duplication cyst with a communication, reapproximation of the esophageal mucosa is a paramount consideration; in our view, this is best done through an open approach.

In cases of suspected leiomyoma of the esophagus, preoperative investigation should be done to confirm the presence of intact overlying mucosa, which is virtually pathognomonic of this disease. Esophagoscopy is done to assess the mucosa; if the mucosa is intact, the possibility of malignancy is essentially ruled out. Simultaneously, endoscopic ultrasonography may be performed to establish the depth to which the esophageal wall is involved. With a preoperative diagnosis of probable leiomyoma, VATS is the approach of choice in our practice.

So-called dumbbell neurogenic tumors (tumors that invade the neural foramen) are special cases. Any solid mass in the costovertebral sulcus should be evaluated by means of MRI to determine whether it is invading the neural foramen if the absence of invasion was not clearly established by CT. Although invasion of the neural foramen by tumor is not in itself an indication for thoracotomy, it does necessitate a combined anterior-posterior approach with neurosurgical involvement for the intraspinal portion of the procedure. Several versions of such an approach have been described.^{27–29} We prefer to perform the posterior neurosurgical resection of the intraspinal component (laminectomy and intervertebral foraminotomy) first and then to reposition the patient and carry out the remainder of the procedure (generally via VATS).³⁰

Although VATS is often an excellent approach to posterior mediastinal lesions, it must be emphasized that one should never hesitate to convert a VATS procedure to a thoracotomy if required. Accordingly, informed consent to undergo thoracotomy should be sought before operation from all patients being treated for posterior mediastinal lesions, even when VATS is the intended approach.

VATS RESECTION OF NEUROGENIC TUMOR OF POSTERIOR MEDIASTINUM

Operative Technique

Resection of a solid neurogenic tumor of the posterior mediastinum that does not invade the neural foramen [see Figure 9] proceeds as follows.

Step 1: intubation and endoscopy The patient is intubated with a double-lumen endotracheal tube to allow single-lung ventilation. Preoperative bronchoscopy (for cystic lesions) or esophagoscopy (for lesions abutting the esophagus) is performed as indicated (see above).

Step 2: patient positioning and placement of ports The patient is placed in the lateral thoracotomy position and stabilized with bean bags so that the operating table can safely be tilted as much as 45° to either side. With this degree of tilt, the lung tends to fall away from the field of vision; thus, there usually is no need to place an additional port for a lung retractor.

The port for the scope is placed through an incision in the midaxillary line at the level of the mass; if it is placed much more anteriorly than the midaxillary line, the surgeon's view of posterior lesions may be obscured by the lung. The two working ports are placed through separate incisions in the posterior axillary line, made as far cephalad and caudad as possible. Sometimes placement of an alternative upper working port posterior to the scapula is advantageous [see Figure 10]. The main working instruments are an endoscopic scissors-cautery, a ring clamp, an endoscopic peanut dissector, a Maryland dissector, a long right-angle clamp, and an endoscopic clip applier.

Step 3: incision of pleura The parietal pleura is incised around the mass, with a margin of approximately 2 cm circumferentially. The pleura is tented up with the aid of

Figure 9 Resection of neurogenic tumor of posterior mediastinum. Intraoperative photograph shows a solid neurogenic tumor of the costovertebral sulcus.

Figure 10 Resection of neurogenic tumor of posterior mediastinum. Shown is typical port placement for video thorascopic resection of a posterior mediastinal mass.

the right-angle clamp or the Maryland dissector to separate it from the underlying structures [see Figure 11]. This separation allows the use of the electrocautery, which provides

Figure 11 Resection of neurogenic tumor of posterior mediastinum. Shown is circumferential incision of the pleura around a neurogenic mass.

hemostasis while protecting the underlying esophagus, vagus and intercostal nerves, and azygos vein. This dissection and all subsequent work are facilitated by placing gentle traction on the mass with a sponge stick or, for smaller masses, by grasping the entire mass within a ring clamp.

Step 4: dissection of soft tissue attachments Once the pleura has been incised circumferentially, the soft tissue attachments are further dissected bluntly with the endoscopic peanut dissector. Attachments that are relatively thick or vascular are best controlled by double-clipping and division. If the tumor originates from an intercostal nerve, gentle dissection is done beneath the tumor to identify the intercostal bundle that is the source of the lesion.

Step 5: division of source intercostal bundle The source intercostal bundle lateral to the tumor is mobilized, doubly clipped, and divided. Once this has been accomplished, blunt dissection is performed until the nerve root emerging from the neural foramen and the associated intercostal vessels are the last remaining attachments. If the tumor originates from the sympathetic chain, the chain is clipped above and below the tumor, and the intercostal bundle is spared if possible.

Step 6: removal of specimen The remaining stalk is doubly clipped and divided [see Figure 12], and the mass is removed in an endoscopic bagging device.

Step 7: drainage A 24 French chest tube is positioned posteriorly at the apex.

Troubleshooting

Care must be taken to ensure that only very gentle traction is exerted on a mass adjacent to the neural foramen. Overzealous traction can cause tearing of the nerve root proximal to the extraspinal extent of the dura, and this tearing can lead to a cerebrospinal fluid (CSF) leak, which most often becomes evident only postoperatively (in the form of persistent clear

Figure 12 Resection of neurogenic tumor of posterior mediastinum. The final remaining intercostal stalk is divided.

chest tube output). The diagnosis of CSF leakage can be confirmed by measuring the β_2 -transferrin level in the fluid. If CSF leakage is confirmed, reoperation with a neurosurgeon is mandatory; the leak is repaired and buttressed with vascularized tissue.

After resection of a tumor at the costovertebral sulcus, regular neurologic examinations of the lower extremities are indicated. Tamponade with hemostatic agents should never be employed for bleeding at the neural foramen: doing so can result in an intraspinal hematoma with subsequent cord compression. Careful use of the electrocautery at the bony margins of the foramen or watchful waiting is preferable. If hemostasis cannot be achieved with these measures, a neurosurgical consultation should be obtained. In the event of oozing from the vicinity of a foramen that is not easily controlled, there should be no hesitation in converting a VATS procedure to an open procedure.

In a minority of patients, clipping and division of an intercostal nerve result in intercostal neuralgia after the procedure; the possibility that this may occur must be discussed with the patient preoperatively. Many patients who undergo division of a lower thoracic intercostal nerve that supplies an upper abdominal dermatome notice postoperative bulging of the ipsilateral abdomen in the area supplied by that nerve.

RESECTION OF BENIGN CYST OF POSTERIOR MEDIASTINUM

Resection of a benign cystic mass of the posterior mediastinum closely resembles resection of a neurogenic tumor [see Resection of Neurogenic Tumor of Posterior Mediastinum, *above*]; the differences are relatively minor [see Troubleshooting, *below*].

Troubleshooting

In the initial stages of dissection of a benign cyst of the posterior mediastinum, care should be taken not to rupture the cyst; initial mobilization from surrounding structures is easier when the cyst wall is under tension [see Figure 13]. If the area of

Figure 13 Resection of benign cyst of posterior mediastinum. Intraoperative photograph shows a fluid-filled posterior mediastinal cyst. The tenseness of the cyst wall facilitates initial dissection.

the cyst wall that directly abuts the mediastinum is found to be too adherent to underlying structures to be removed safely, we intentionally rupture the cyst and then remove as much of the cyst wall as possible. As much as 35% of the cyst wall may be left in place. In such cases, we ablate the residual intact cyst wall with the electrocautery to destroy any potential secretory tissue. In our estimation, if more than approximately 35% of the cyst must be left in place, conversion to thoracotomy should be considered.

RESECTION OF ESOPHAGEAL LEIOMYOMA

Operative Technique

In addition to the steps described for resection of a neurogenic mass, there are several special maneuvers that facilitate resection of esophageal intramural masses, such as leiomyomata [see Figure 14a] and duplication cysts:

1. The pleura is incised longitudinally with the electrocautery after it is tented up away from the esophagus, the vagus nerve, and the azygos vein with a right-angle clamp or a Maryland dissector [see Figure 14b].
2. In some cases, exposure is facilitated by dividing the azygos vein with an endoscopic stapler [see Figure 14c].
3. The longitudinal esophageal muscle fibers that overlie the mass are separated bluntly or with the electrocautery in the line of the fibers. These fibers are often markedly attenuated as a result of the expansion of the mass [see Figure 14d].
4. Blunt dissection with an endoscopic peanut dissector allows careful, progressive mobilization of the mass, first from the muscle layer and then from the underlying mucosa. Gentle traction on the mass facilitates exposure at this point in the procedure [see Figure 14e]. A suture may be placed into the tumor to facilitate this retraction. Having an assistant place the endoscope within the esophageal lumen to distend and illuminate the mucosa also may be helpful at this stage. Once the mass has been completely resected, it is sent for pathologic examination [see Figure 14f].
5. The esophagus is distended by insufflating air from above while the distal esophagus is occluded with a sponge stick. The air-filled esophagus is then submerged in saline, and the area of the resection is examined for air leakage.

Troubleshooting

The muscular defect in the esophageal wall must be closed after resection to ensure that an esophageal diverticulum will not develop. Such closure may be accomplished by means of thoracoscopic suturing.

Frequently, duplication cysts are more adherent to the underlying esophageal mucosa than leiomyomata are, and transillumination of the esophageal wall helps define the plane at which blunt dissection should be performed. Where the cyst wall becomes difficult to separate from the mucosa, a small amount of the wall may be left in place if, in the surgeon's judgment, attempting to remove all of it might lead to a breach in the mucosa.

Financial Disclosures: None Reported.

12 PERICARDIAL PROCEDURES

Dawn Emick, MD, and Thomas A. D'Amico, MD

Surgical procedures are performed on the pericardium either for diagnostic purposes or for relief of the hemodynamic consequences of pericardial disease. The pericardial processes for which surgical intervention is required can be divided into two broad categories: pericardial effusion and constrictive pericarditis. Pericardial effusion can either be acute or chronic, and the management of effusion depends largely on the rapidity of fluid accumulation and the risk of cardiac tamponade. The decisions that must be made regarding the selection of patients, the timing of surgery, and the choice of technique or approach often pose substantial challenges to the surgeon. Accordingly, a thorough knowledge of the anatomy, physiology, and pathophysiology of the pericardium is essential for successful management of pericardial disease processes.

Anatomic and Physiologic Considerations

ANATOMY

Like the pleura, the pericardium consists of two layers. The inner layer, the visceral pericardium (or epicardium), is a monolayer of mesothelial cells that is adherent to the heart. The outer layer, the parietal pericardium, is a tough fibrous structure composed of dense bundles of collagen fibers with occasional elastic fibers. The fibrous structure of this layer renders the pericardial sac relatively noncompliant, and this noncompliance plays a significant role in pericardial function and pathophysiology.

The pericardium surrounds the heart and the great vessels [see Figure 1]. Its parietal and visceral surfaces meet superiorly at the ascending aorta and the superior vena cava. From that point, the pericardium continues down the right border of the heart and over the anterior surface of the pulmonary veins to the inferior vena cava. After crossing the inferior vena cava, the inferior pericardium is densely adherent to the diaphragm. Just past the apex of the heart, it turns superiorly again and runs over the pulmonary veins back to the aorta.

Anteriorly, there are normally no connections between the visceral and parietal layers of the pericardium. Posteriorly, the pattern of pericardial reflections around the pulmonary veins and the venae cavae creates two sinuses. The oblique pericardial sinus is the space in the center of the pulmonary veins, directly behind the left atrium. The transverse pericardial sinus is bordered anteriorly by the aorta and the main pulmonary artery and posteriorly by the dome of the left atrium and the superior vena cava.

NORMAL PHYSIOLOGY

The pericardium is normally filled with 15 to 50 mL of serous fluid, which serves as lubrication to facilitate the motion of the heart within this structure. By virtue of its

relative noncompliance, the pericardium exerts an influence on cardiac hemodynamics. This influence can easily be seen in the normal inspiratory variation in systemic arterial pressure. Under normal circumstances, intrapericardial pressure is slightly less than 0 mm Hg, becoming more negative during inspiration and less negative during expiration. Negative intrathoracic pressure during inspiration augments right ventricular filling. Because the pericardium does not allow significant acute right ventricular dilation, the ventricular cavity enlarges by shifting the septum toward the left ventricle. In addition, the noncompliance of the pericardium prevents the free wall of the left ventricle from distending to recapture its normal cavity volume. Thus, the volume ejected from the left ventricle is slightly decreased, resulting in lower systemic arterial pressure. Normally, this effect is exceedingly small. However, it becomes more pronounced when the pericardium is filled with fluid: ventricular distention is restricted even further, and paradoxical pulse becomes clinically apparent.

PATHOPHYSIOLOGY

Although the pericardium is resistant to rapid distention, it is capable of distending over time. If filled slowly, it can expand to contain significant amounts of fluid (sometimes more than 1 L) before hemodynamic consequences develop. In the setting of an acute pericardial effusion (e.g., from trauma), however, devastating hemodynamic consequences may occur with only 100 to 200 mL of blood in the pericardium. When the elastic capacity of the pericardium is exceeded, even small increases in volume cause large increases in intrapericardial pressure and, if untreated, can lead to rapidly fatal cardiac tamponade. Although large, chronic effusions accumulate slowly over time, there is still a point at which the pericardium can no longer accommodate more volume, and tamponade can develop quickly. In a series of 28 patients with large idiopathic pericardial effusions, nearly 30% developed cardiac tamponade unexpectedly.¹ Thus, drainage of large effusions even without signs of tamponade may be appropriate, particularly if there is evidence of right-sided diastolic collapse. A number of different processes can result in the accumulation of fluid in the pericardial space [see Table 1].

Constrictive pericarditis is defined as a chronic fibrous thickening of the pericardium that causes cardiac compression sufficient to prevent normal diastolic filling. It can best be thought of as the chronic sequela of acute pericarditis or of any situation resulting in pericardial irritation and adhesion formation. Almost any cause of acute pericarditis can result in pericardial constriction [see Table 2]. In many patients, there is no clear antecedent event, and the cause of the constrictive pericarditis cannot be determined with certainty.

Figure 1 Shown is a view of the pericardium with the heart removed.

Pathologic examination typically demonstrates end-stage fibrosis, and these cases are presumed to be viral in origin. Historically, mycobacterial tuberculosis has been the most common infectious cause of constrictive pericarditis, and it is still the dominant infectious cause in many developing countries today.^{2,3} In the United States, tuberculosis is the cause of constrictive pericarditis in approximately 6% of patients who undergo pericardiectomy.⁴ Constrictive pericarditis also occurs after instrumentation of the pericardium and is seen occasionally (in 0.2 to 0.3% of cases) after cardiac surgery.^{5,6} It also may develop after iatrogenic cardiac perforation in the course of catheterization or pacemaker

placement and after blunt or penetrating trauma—essentially, after any process resulting in an incompletely drained hemopericardium.^{7,8}

The pericardium may harbor metastatic disease or locally advanced disease (e.g., mesothelioma), which may lead to pericardial constriction.^{9,10} Connective tissue disorders (e.g., rheumatoid arthritis and lupus) can cause recurrent acute pericarditis and pericardial effusions, eventually resulting in constrictive pericarditis. A similar situation may arise in patients receiving radiation therapy and patients with renal failure.

The stiffening and thickening of the pericardium have three major physiologic effects. First, the thicker pericardium isolates the heart from changes in intrathoracic pressure. Normally, the pulmonary veins (which are intrathoracic structures) and the cardiac chambers experience the same changes in intrathoracic pressure. In the presence of pericardial constriction, however, the negative intrathoracic pressure generated during inspiration cannot be transmitted to the heart. This isolation of the heart results in decreased flow through the pulmonary veins during inspiration and reduced left-side filling.

Second, the ventricles become interdependent. Because total pericardial volume does not change, the inspiratory decrease in left ventricular filling seen with constriction must be accompanied by an increase in right ventricular filling, with a resultant septal shift toward the left ventricle. During expiration, the opposite occurs: left ventricular filling increases and right ventricular filling decreases, and there is a septal shift toward the right ventricle.

Third, the encasement of the heart impairs the diastolic filling of all cardiac chambers. Elevated atrial pressure causes rapid initial filling of the ventricle (with as much as 75% of the ventricle filled during the first 25% of diastole), but by the middle of diastole, filling abruptly decreases as a result of the rigid pericardium. Because of this limit to diastolic filling, increasing the heart rate becomes the most effective method of increasing cardiac output.¹¹

Other uncommon but potentially significant pericardial diseases include congenital defects and cysts. In one study, congenital defects of the pericardium were found in 1 of 10,000 autopsies.¹² Most commonly, these included partial or total absence of pericardium on the left (70%), right (17%), or total bilateral (rare), and 30% had other associated anatomic anomalies. Most patients with complete absence or large defects are asymptomatic; partial left-sided defects can be complicated by herniation of the heart through the defect and possible strangulation leading to chest pain, shortness of breath, syncope, or sudden death. Surgical pericardioplasty may be indicated in patients with imminent strangulation. Pericardial cysts may be congenital, inflammatory, or echinococcal in origin. Regardless of origin, most cysts are asymptomatic and detected incidentally. Patients with symptoms from compression on the heart are candidates for percutaneous aspiration and ethanol sclerosis, with the addition of pretreatment with albendazole for echinococcal cysts.¹³ Patients with symptomatic inflammatory or congenital cysts who do not respond to aspiration and sclerosis may be candidates for video-assisted thoracotomy or surgical excision.

Pericardial Drainage Procedures for Pericardial Effusion

Pericardial effusion fluid may be transudate, exudate, pyopericardium, or hemopericardium. Regardless of the origin of the fluid accumulation, once the pericardium has reached the limits of its elasticity, the only way in which it can increase its volume is by reducing the volume occupied by the heart within it. Increases in pericardial pressure result in progressive cardiac compression and reductions in intracardiac volumes and myocardial diastolic compliance. This effect is most pronounced in the chambers with the lowest normal intracavitary pressures—namely, the right atrium and the right ventricle.¹⁴ Changes in systemic cardiac output occur as a result of right heart compression, which leads to diminished right ventricular stroke volume, reduced pulmonary blood flow, and decreased left ventricular filling. In the early stages of pericardial effusion, various compensatory changes act to preserve cardiac output. Such changes include an increased ejection fraction, tachycardia, increased intravascular volume via renal conservation of salt and water, increased peripheral vascular resistance, and time-dependent pericardial stretch.^{15,16}

PREOPERATIVE EVALUATION

The presenting symptoms of pericardial effusion may be nonspecific and related to the underlying disorder (e.g., fever, chest pressure, and fatigue). Fluid accumulation that is substantial enough to have hemodynamic consequences is defined as cardiac tamponade. Patients with early tamponade may have dyspnea, tachycardia, mild hypotension, decreased urine output, and paradoxical pulse. As tamponade progresses, patients may manifest signs of end-organ hypoperfusion (e.g., mental status changes, renal insufficiency, and shock). The classic physical findings known as the Beck triad (i.e., jugular venous distention, systemic hypotension, and distant heart sounds) are more common with acute tamponade (such as results from trauma) than with slow-developing tamponade (such as results from medical processes). In patients with slow-developing tamponade, systemic fluid retention is observed, often manifested by peripheral edema or ascites.

Most commonly, pericardial effusion is diagnosed when a patient exhibits new symptoms in the context of an underlying disorder associated with pericardial effusion (e.g., renal failure or malignancy). Chest x-rays may reveal a globular heart or an increasing cardiac silhouette on serial films. Currently, echocardiography is the most commonly employed and most useful modality for the diagnosis of pericardial effusion: it reliably determines the presence, location, and relative volume of fluid accumulations. The size of effusions can be graded based on echocardiographic findings. Grade I effusions are small (echo-free space in diastole <10 mm), grade II effusions are moderate (10 to 20 mm), grade III are large (≥ 20 mm), and grade IV are very large (≥ 20 mm and compression of the heart).¹⁷ In many cases, echocardiography can identify early tamponade, often before symptoms develop. A variety of echocardiographic findings are helpful in diagnosing hemodynamically significant effusions, the most useful being right atrial collapse and right ventricular collapse. Right atrial collapse during late diastole tends to occur early in the development of tamponade because of the normally low right

atrial filling pressures. Right ventricular free wall collapse during early diastole suggests progression of tamponade. Other useful signs are loss of the normal inspiratory collapse of the inferior vena cava and an increase in right ventricular diameter with a reciprocal decrease in left ventricular diameter during inspiration.

In patients who are undergoing invasive hemodynamic monitoring (e.g., those who have just undergone cardiac surgery), hemodynamic findings suggestive of tamponade include elevation of right atrial pressure and equalization of right atrial pressure and pulmonary capillary wedge pressure. It is important to remember, however, that localized tamponade can occur (especially in the postoperative period) without these changes. A common cause is localized clot in the oblique pericardial sinus behind the left atrium, which causes reduced left atrial compliance. Transesophageal echocardiography here may be particularly useful, but it is important to have a high degree of suspicion in these cases as thrombosis does not have the typical echolucent area on echocardiography.

OPERATIVE PLANNING

Choice of Procedure

Three procedures are commonly performed for surgical diagnosis and treatment of pericardial effusion: pericardiocentesis, subxiphoid pericardiostomy (pericardial window), and thoracoscopic pericardiostomy (via either the right or the left pleural space). The choice of a surgical approach to the pericardial space depends on the clinical condition of the patient, the presence or absence of associated pleural effusion or other thoracic process, and the underlying diagnosis (if known). Patients with tamponade may decompensate rapidly during the vasodilatation and positive pressure ventilation associated with general anesthesia. Accordingly, careful consideration must be given to the type of anesthesia employed for pericardial drainage procedures.

Pericardiocentesis is routinely done with local anesthesia only and may be the best choice in an acutely unstable patient with tamponade. If this option is chosen, however, the choice must be made with the understanding that pericardiocentesis, because of its high recurrence rate and its limited diagnostic capacity, is unlikely to constitute definitive therapy. Subxiphoid pericardiostomy is generally done with initial local anesthesia followed by induction of general anesthesia, and most patients with tamponade can undergo this procedure. The subxiphoid approach provides the hemodynamic benefits of pericardiocentesis, offers the enhanced diagnostic capability of pericardial biopsy, and has a low recurrence rate. Consequently, it is the procedure of choice for patients with tamponade who are stable enough to be transported to the operating suite. Thoracoscopic pericardiostomy has the advantage of enabling simultaneous treatment of pleural processes, which are commonly present in these patients [see *Figure 2*]. Ipsilateral pleural and pericardial spaces can be fully explored, pleural effusions can be drained, loculations can be divided, and biopsy specimens can be obtained as needed. The thoracoscopic approach can be especially useful in the case of a known loculated effusion that is limited to one area of the pericardium, in that a pericardial window can be created via either pleural space. This approach also allows resection of a larger segment of pericardium, which may

Figure 2 Computed tomography demonstrates right pleural and pericardial effusions, for which a right thoracoscopic approach is ideal.

improve the diagnostic yield and reduce the likelihood of recurrent effusion. The major limitation of thoracoscopic pericardiostomy is the need for lung isolation and lateral positioning, which should not be attempted in patients with evidence of tamponade. By weighing the relative risks and benefits of these three procedures, the surgeon can choose the optimal approach for each patient.

PERICARDIOCENTESIS

Operative Technique

Pericardiocentesis is performed either at the bedside in an urgent situation or, preferably, under echocardiographic or fluoroscopic guidance in a catheterization laboratory. The basic technique is simple.

Step 1: placement of needle A local anesthetic is infiltrated along the left side of the xiphoid. An 18-gauge spinal needle attached to a three-way stopcock and syringe is then advanced into the pericardial space and directed cephalad toward the left shoulder at a 45° angle until fluid is aspirated [see *Figure 3*]; if air is aspirated, the needle is withdrawn and redirected more medially. Once fluid is aspirated freely, it is inspected. If the fluid is bloody, 5 mL is withdrawn and placed on a sponge. If the fluid on the sponge clots, it is fresh blood, probably from a cardiac injury occurring during the procedure or from intracardiac positioning of the needle; blood that has been in the pericardium for even a short time becomes defibrinated and will not clot.¹⁸

Troubleshooting The inherent danger of cardiac injury during pericardiocentesis should be obvious. The risk is highest with small or loculated effusions and patients with coagulation abnormalities. The possibility of cardiac aspiration or injury can be minimized, although not eliminated, by means of various safety measures. Of historical interest, the simplest of these measures was to attach an electrocardiographic (ECG) lead to the needle and employ continuous ECG monitoring. If the needle contacts the epicardium, ST

Figure 3 Pericardiocentesis. The needle is angled toward the left shoulder at an angle of 45°.

segment elevation will be observed, in which case, the needle is withdrawn until the ST elevation disappears. This is not considered to be an adequate safeguard anymore, and most experts recommend direct visualization using fluoroscopic or echocardiographic guidance. Fluoroscopy or echocardiography is essential in cases of loculated effusions to help direct aspiration. Simultaneous cardiac catheterization has also been used to locate the right coronary artery and the atrioventricular groove.

Step 2: placement of drainage catheter and aspiration of fluid Once the needle is within the pericardial space, a guide wire is placed through it, and a small-bore drainage catheter is advanced into the effusion by means of a modified Seldinger technique. Fluid is aspirated and sent for laboratory evaluation (including cell count, chemistry, culture, and cytology). The catheter is then connected to a closed drainage system for 24 to 72 hours; this may help reduce recurrence.

Complications

The most serious complications of pericardiocentesis are laceration and/or rupture of the myocardium and coronary vessels. Thankfully, these are rare (<1% when fluoroscopy is used).¹⁹ More common complications of pericardiocentesis include arrhythmias, pneumothorax, air embolism, puncture of the abdominal cavity or abdominal organs, misdiagnosis, and recurrence of pericardial effusion. In every patient undergoing pericardiocentesis, pneumothorax must be ruled out by means of chest x-ray at the completion of the procedure or, if respiratory or hemodynamic changes develop intraoperatively, during the procedure. Cardiac injuries range from minor needle lacerations to the epicardium, which are self-limited in patients with normal coagulation parameters, to potentially fatal injuries to the myocardium or coronary vessels that can lead to acute cardiac tamponade. Incorrect diagnoses based on pericardiocentesis are not uncommon.

Although a diagnosis can be confirmed by positive results from fluid culture or cytology, negative results from cytology do not rule out malignant effusion. Cytologic analysis of pericardial fluid is diagnostic in only 55 to 85% of patients.²⁰ Further diagnostic maneuvers often must be undertaken, usually involving subxiphoid or thoracoscopic approaches with pericardial biopsy. Recurrence of pericardial effusion after pericardiocentesis is extremely common. In a review that included 139 patients with malignant pericardial effusions who were treated with pericardiocentesis, successful fluid removal with symptomatic relief was achieved in 97.1% of cases.²¹ Of the 139 patients, 2.9% experienced complications (e.g., pneumothorax and ventricular laceration) and one (0.7%) died. In all, 45 of the patients received no further therapy, and in 25 (55%) of the 45, recurrent effusions developed that necessitated reintervention.

Several techniques for preventing recurrent pericardial effusion have been tried. Instillation of a sclerosing agent (e.g., tetracycline, thiopeta, or bleomycin) into the pericardium to promote fusion of the two layers of the pericardium has been shown to increase the success rate of pericardiocentesis by as much as 85%.^{22–24} Placement of an indwelling catheter (see above) also has been shown to improve the success rate.^{21,25} Several authors have described creating a pericardial window percutaneously by means of balloon dilation of the tract created by pericardiocentesis, which theoretically allows fluid to drain into the pleural space or the subcutaneous tissues, where it can be absorbed.^{26,27} However, it is unclear how long a window created in this fashion will remain patent. Although pericardiocentesis provides initial symptomatic relief in most patients, the observation that 15 to 45% of patients require a further procedure for diagnosis and as many as 55% require reintervention for recurrence has led some authorities to question its benefit.

SUBXIPHOID PERICARDIOSTOMY (PERICARDIAL WINDOW)

Operative Technique

Subxiphoid pericardiostomy may be performed either to diagnose pericardial effusion or to manage tamponade. For diagnosis, the procedure is usually done with general anesthesia. In an unstable patient with significant tamponade, who would be at risk for hemodynamic collapse with general anesthesia, the procedure may be performed with the patient under local anesthesia and mild sedation and breathing spontaneously. If there is any question of tamponade, the patient is prepared and draped while awake, and anesthesia is induced only when the surgeon is ready to begin. In all patients, the entire chest should be prepared in case a left anterior thoracotomy or median sternotomy is required. Ideally, the patient is sedated and the airway controlled while spontaneous respiration is maintained to minimize hemodynamic effects. If necessary, a local anesthetic may be infiltrated and the incision made before induction of anesthesia.

Step 1: initial incision and exposure of pericardium

A small vertical incision is made from the xiphisternal junction downward to a point slightly below the tip of the xiphoid process [see Figure 4a]. The upper extent of the linea alba is divided, with care taken not to enter the peritoneum. Peritoneal openings are easily repaired but can make the

Figure 4 Subxiphoid pericardiostomy. (a) A small vertical incision is made from the xiphisternal junction down to a point just below the tip of the xiphoid, the upper extent of the linea alba is divided, and the xiphoid is removed. (b) The pericardium is opened, and the edge of the opening is grasped and elevated. A pericardial specimen several square centimeters in size is then resected to create the pericardial window.

procedure technically more difficult in that abdominal contents tend to impede visualization, especially in spontaneously breathing patients. Positioning patients with feet down in a reverse Trendelenburg position prior to the procedure may allow the abdominal organs to fall toward the pelvis and out of the way. The soft tissue attachments to the xiphoid are divided, the veins running along either side of the xiphoid are controlled, and the xiphoid process is removed.

The tissue plane behind the lower sternum is developed by means of blunt dissection. This maneuver exposes the retrosternal space to allow visualization of the pericardium. To enhance exposure, the sternum is retracted upward by an assistant. The anterior pericardial surface is then exposed by sweeping away the remaining mediastinal fat. If necessary, the confluence of the pericardium and the diaphragm may be retracted caudally to improve exposure.

Step 2: opening of pericardium The location of the pericardial incision can be confirmed by palpating cardiac motion through the exposed pericardium. The pericardium is then opened with a scalpel; shallow strokes should be employed to reduce the chances of injuring underlying myocardium that may be adherent to the pericardium. Upon entry into the pericardium, there is an initial outrush of fluid. A sanguineous effusion can be difficult to differentiate from

cardiac injury; therefore, the patient's hemodynamics should be carefully monitored during this time. When the pressure placed on the heart by an effusion is released, blood pressure will usually rise and heart rate fall; however, if the heart has been accidentally injured, the opposite will occur. Once hemodynamic stability is achieved, administration of a diuretic (e.g., furosemide) should be considered to reduce the risk of pulmonary edema developing as a result of systemic fluid retention.

Step 3: creation of pericardial window Pericardial fluid is collected for microbiologic and cytologic analysis and for any additional testing suggested by the clinical scenario. The pericardial space is gently explored with the fingers, and all remaining fluid is evacuated. The edge of the pericardial opening is grasped with a clamp and elevated [see Figure 4b]. A pericardial specimen several square centimeters in size—or as large as can safely be managed—is resected and sent for pathologic and microbiologic analysis.

Step 4: drainage and closure A separate stab incision for drain placement is made below and to one side of the lowermost aspect of the skin incision. Bringing the drainage tube out through a separate incision helps prevent incisional complications (e.g., infection and hernia). A 24 to 28 French

chest tube (either straight or right-angle) is tunneled through the fascia at the entry site so that it lies beneath the divided linea alba in the preperitoneal space. The tube is then directed through the pericardial window and into the pericardial space and secured at skin level. The fascia at the linea alba is closed with interrupted sutures to provide secure closure and prevent late hernia; the skin and subcutaneous tissue are closed in the standard fashion. The chest tube is connected to a drainage system with a water seal. Pericardial drainage is maintained for several days postoperatively until the output falls below 100 mL/day. This period allows time for apposition and adhesion formation between the visceral pericardium and the parietal pericardium.

Although some fluid may initially drain into the subcutaneous tissues and be absorbed, the name pericardial window is something of a misnomer. The surgically created window in the pericardium is unlikely to remain patent over the long term, and, in fact, obliteration of the pericardial space has been shown to be the mechanism responsible for the success of this procedure.^{28,29}

Complications

Complications from subxiphoid pericardiostomy are rare; bleeding, infection, incisional hernia, anesthetic complications, and cardiac injury have been reported. In a study that included 155 patients who underwent subxiphoid pericardiostomy over a 5-year period, not a single death was attributable to the operative procedure itself.²³ The 30-day mortality was high but was related to the underlying disease process: 33% in patients with malignant effusions and 5% in those with benign effusions. Recurrent pericardial effusion necessitating additional procedures occurred in four patients (2.5%). In a study that compared 94 patients who underwent subxiphoid pericardiostomy with 23 patients who underwent pericardiocentesis, the rate of recurrent effusion that necessitated reintervention was 1.1% after the subxiphoid window procedure but 30.4% after pericardiocentesis.³⁰ In this series, the rate of major complications after the pericardial window procedure was 1.1% (one patient with bleeding that necessitated reexploration), compared with a major complication rate of 17% after pericardiocentesis (including a mortality of 4%).

Several studies have shown that the most important predictor of long-term outcome is the underlying disease process. In one, the median survival time was 800 days for patients with benign disease, 105 days for patients with known cancer but negative results from pericardial cytology and pathology, and only 56 days for patients with malignant effusions.²⁸ It appears, however, that cancer patients with hematologic malignancies and pericardial effusion survive significantly longer than patients with other malignancies. In another study, the mean survival time after drainage of pericardial effusion was 20 months for patients with hematologic malignancies, compared with 5 months for patients with any other malignancies.³¹ The investigators suggested that this finding may be related to the relative responsiveness of hematologic cancers to systemic chemotherapy. Patients with HIV disease have been shown to have universally dismal outcomes after they present with pericardial effusion. In this population, surgical pericardial drainage generally is not diagnostically revealing and is of little therapeutic value. Several authors

have questioned whether pericardial drainage should even be offered to these patients.³²

THORACOSCOPIC PERICARDIOSTOMY

Operative Technique

Thoracoscopic pericardiostomy is a safe and effective approach to the diagnosis and management of pericardial effusion, especially in patients with a unilateral pleural disease process that can be simultaneously addressed in the course of the procedure. Thoracoscopic pericardial drainage necessitates single-lung ventilation and thus is unsuitable for unstable patients, especially those with tamponade. Such ventilation can be accomplished by means of either a dual-lumen endotracheal tube or a bronchial blocker placed through a standard endotracheal tube.

Once the tube is in place, the patient is turned to the appropriate lateral decubitus position. The side of approach is chosen on the basis of the location of a loculated effusion or the site of any coexisting pathologic condition (e.g., a pleural effusion, pleural nodules or thickening, or pulmonary nodule). If the disease process or processes present do not dictate a particular side of approach, the right side is preferred. It is often easier to operate on the right side because there is more working room within the pleural space; however, operating on the left side usually allows the surgeon to create a larger pericardial window. If tamponade is present in a patient for whom the thoracoscopic approach is desired, pericardiocentesis may be performed before induction of general anesthesia.³³

Step 1: placement of ports and entry into pleural space An initial camera port is placed in the posterior axillary line at the eighth intercostal space [see Figure 5]. The pleural space is entered and explored, and any effusion present is drained. Pleural fluid is sent separately for culture and cytologic analysis. To prevent inadvertent entry into the pericardium, which is often distended, a second incision is created anteriorly at the fifth intercostal space under camera visualization.

Step 2: opening of pericardium On the left side, the phrenic nerve, which runs midway between the hilum and the anterior chest wall, is carefully identified, and an initial pericardial incision is made approximately 1 cm anterior to this nerve. Care must be taken to place this first incision in an area that is free of cardiac adhesions. When grasped, the pericardium should tent outward slightly. Often cardiac motion is visible through the pericardium.

Step 3: creation of pericardial window A pericardial window several square centimeters in area is removed. A similar window may be created posterior to the phrenic nerve—again, with care taken to stay at least 1 cm away from the nerve. The pericardial space is inspected, and any loculations are opened. The procedure is similar when performed on the right side, except that the phrenic nerve on the right runs much closer to the hilum; accordingly, instead of two pericardial windows (anterior and posterior to the nerve), only a single, larger pericardial window is created (anterior to the nerve).

Figure 5 Thoracoscopic pericardiostomy. Shown are the appropriate patient positioning and the proper placement of ports and instruments.

In patients who can tolerate general anesthesia, a pericardial window can be created thoracoscopically with excellent diagnostic yield and relief of symptoms.³⁴ The thoracoscopic approach allows directed access and can be useful in treating effusions that recur after subxiphoid pericardiostomy.³⁵

Complications

Complications from thoracoscopic pericardiostomy occur more frequently than from the subxiphoid approach. Reported complications include bleeding, infection, and cardiac injury similar to the subxiphoid approach, but compared to the subxiphoid approach, patients who undergo thoracoscopic procedures have longer anesthesia times and require single-lung ventilation, which increases the incidence of anesthesia-related complications. Patients who undergo thoracoscopic procedures require pleural tubes in the immediate postoperative period, and various complications related to chest tubes (e.g., recurrent pneumothorax, trapped lung) may occur. One recent study compared subxiphoid to videothoracoscopic pericardial window procedures in 71 patients.³⁶ In this retrospective review, 56 patients underwent subxiphoid pericardiostomy and 15 underwent the procedure thoracoscopically. Nonpericardial procedures were performed in 10 of 15

thoracoscopic procedures (67%) and only 18 of 56 (32%) of the subxiphoid approach. Anesthesia time (117 ± 32 vs 81 ± 26 minutes) and minor procedural morbidity (27% versus 2%) were higher for the thoracoscopic approach, but long-term control of the effusion seemed to be improved in the thoracoscopic approach. Equal percentages of patients had recurrence of their effusions ($\approx 10\%$), but time to recurrence was much longer for the thoracoscopic procedures (36 versus 11 months).

Pericardiectomy for Constrictive Pericarditis

Constrictive pericarditis appears to be about three times as common in males as in females, and it may occur at any point in life from childhood to the ninth decade.³⁷ The symptoms of constrictive pericarditis usually develop progressively over a period of years but may develop within weeks to months after a defined inciting event (e.g., mediastinal irradiation or cardiac surgery). Signs and symptoms are related to pulmonary venous congestion (e.g., exertional dyspnea) and systemic venous congestion (e.g., elevated jugular venous pressure, hepatomegaly, ascites, and peripheral edema).

PREOPERATIVE EVALUATION

The physiologic effects of the thickened pericardium form the basis for the diagnosis of constrictive pericarditis and, more important, for the differentiation of constrictive pericarditis from restrictive cardiomyopathy, which often presents a similar picture. Echocardiography can be employed to rule out other causes of right-side failure. Specific findings that suggest pericardial constriction include septal bounce (a respiratory phase-related septal shift) and decreased transmitral flow velocity during inspiration. Computed tomography and magnetic resonance imaging may demonstrate thickened, often calcified, pericardium; however, the degree of pericardial thickening does not necessarily correlate with the presence of hemodynamic effects.

Cardiac catheterization may demonstrate increases in and equalization of end-diastolic pressure in all four cardiac chambers, a dip-and-plateau pattern (the square-root sign) in the ventricular pressure curves as a result of rapid early filling and limited late filling, and rapid x and y descents in the atrial pressure curves. The most useful information obtainable through cardiac catheterization has to do with the respiratory variation of ventricular pressure. In a patient with a normal heart or a patient with restrictive cardiomyopathy, inspiration causes a decrease in both right ventricular pressure and left ventricular pressure as a consequence of decreased intrathoracic pressure. In a patient with constrictive pericarditis, because of the interdependence of the ventricles, inspiration causes a decrease in left ventricular pressure but an increase in right ventricular pressure.³⁸

OPERATIVE PLANNING

Choice of Approach

Pericardiectomy may be performed via either a median sternotomy or a left anterolateral thoracotomy, with equivalent results. Median sternotomy provides better access to the right atrium and the great vessels, as well as easier access for cannulation if cardiopulmonary bypass is required; left anterolateral thoracotomy allows more complete release of the left ventricle. With either approach, the patient should undergo full monitoring, including radial artery catheterization and central venous catheterization, with consideration given to placement of a pulmonary arterial catheter if there is significant hemodynamic compromise. Because significant blood loss can occur when densely adherent pericardium is resected, large-bore intravenous access should be available as well.

OPERATIVE TECHNIQUE

Median Sternotomy

Step 1: initial incision and exposure The patient is placed in the supine position, and the skin incision is carried down to the level of the sternum. If there is no history of previous pericardial procedures and it is possible to develop the plane behind the sternum bluntly at the superior and inferior aspects, a standard sternotomy saw can be used for the median sternotomy. If, however, there are likely to be adhesions between the sternum and the pericardium or the heart (as in the case of constrictive pericarditis after coronary artery bypass grafting), a careful reoperative sternotomy

should be performed with an oscillating saw. Access to the femoral vessels should be available within the sterile field; placement of a femoral arterial line will facilitate percutaneous cannulation in the event that the heart is injured during sternal reentry.

After the sternum is opened, all adhesions are dissected away from the sternum, with care taken to stay as close to the posterior surface of the sternum as possible. Both pleural spaces are opened, and the left and right phrenic nerves are identified.

Step 2: dissection and resection of pericardium The phrenic nerves define the limits of pericardial resection bilaterally. Small loculated spaces are often present within the pericardium, especially near the great vessels and the diaphragm, and provide good starting places for pericardiectomy. Once an initial flap is raised, it is used to provide retraction to facilitate further dissection. Careful attention must be paid to the coronary artery anatomy: coronary arteries and bypass grafts are vulnerable to injury. If the pericardium is densely adherent in the region of a coronary artery, small islands of pericardium may be left on the heart. Areas of calcification can be addressed with the use of bone-cutting instruments; however, if an island of calcification appears to extend into the myocardium, it should not be removed.

Figure 6 Pericardiectomy: median sternotomy approach. The pericardium is resected from the left phrenic nerve to the right phrenic nerve.

Epicardium can also be involved in the disease process and should be resected or scored until no further restriction to ventricular filling remains. The heart should be dissected free of the left pulmonary veins all the way over to the right pulmonary veins (including the origins of the venae cavae). The pericardium is resected from the left phrenic nerve to the right phrenic nerve [see *Figure 6*].

Cardiopulmonary bypass can make dissection easier, but in view of the greater risk of bleeding and the increased transfusion requirements, it is best avoided if possible. Cardiopulmonary bypass does facilitate repair of cardiac injuries during sternal reentry or dissection and should be used if cardiac procedures are to be performed concomitantly.

Step 3: drainage and closure After completion of the pericardiectomy, mediastinal and pleural drains are placed, and the sternum is closed in the usual fashion.

Left Anterolateral Thoracotomy

Step 1: initial incision and exposure The patient is placed in the supine position, with a roll under the left side of the torso to elevate the left side 45°. It is often difficult to establish cardiopulmonary bypass through the chest via this approach; therefore, the femoral vessels should be available within the sterile field so that femorofemoral bypass can be instituted if necessary. A curvilinear submammary incision is created, and the chest is entered at the fifth interspace.

For improved exposure, the internal thoracic vessels may be divided and the intercostal muscles divided posteriorly. The left phrenic nerve is carefully identified.

Step 2: dissection and resection of pericardium As with the median sternotomy approach, loculated spaces are often present near the great vessels and the diaphragm, and these vessels provide good starting places for dissection. The entire pericardium is dissected free over the left ventricle, and an island of pericardium is left attached to the phrenic nerve along its length [see *Figure 7*]. The pericardium is resected from the pulmonary veins to a point just posterior to the phrenic nerve. Resection resumes anterior to the nerve and continues across the anterior aspect of the heart as far as possible, ideally to the right atrioventricular groove. The same precautions should be taken around the coronary vessels as are taken with the median sternotomy approach.

Step 3: drainage and closure After completion of the pericardiectomy, mediastinal and pleural drains are placed, and the thoracotomy is closed in the usual fashion.

OUTCOME EVALUATION

There is no proven difference between the two approaches to pericardiectomy with respect to outcome. Accordingly, the choice between them is based on whether one option affords better access to the areas believed to be most involved

Figure 7 Pericardiectomy: left anterolateral thoracotomy approach. (a) The left phrenic nerve is identified. (b) The entire pericardium is dissected free over the left ventricle, with an island of pericardium left attached to the phrenic nerve along its length. Care must be taken to avoid injuring coronary vessels.

(e.g., a median sternotomy is more effective for releasing the right side of the heart) and whether the surgeon is more comfortable with one approach or the other.

The underlying cause of constrictive pericarditis is a significant predictor of long-term survival. In a study of 163 patients who underwent pericardiectomy, 7-year survival rates were highest in patients with idiopathic constrictive pericarditis (88%), somewhat lower in patients with postoperative constriction (66%), and lowest in patients with radiation-induced constriction (27%).³⁹ Predictors of decreased survival included previous radiation therapy, renal dysfunction, pulmonary hypertension, and abnormal left ventricular systolic function. Perioperative mortality was 6% overall but 21% in patients who had received radiation therapy and 8% in postsurgical patients. The slightly higher mortality recorded in postoperative patients may reflect underlying cardiac dysfunction, as well as the vulnerability of previous bypass grafts to injury. The poor outcomes after

pericardiectomy for radiation-induced constriction indicate that constriction is not the sole factor responsible for cardiac failure in this situation. Although cardiac failure has been attributed to myocardial atrophy caused by prolonged constriction, the excellent outcomes reported after pericardiectomy for idiopathic constrictive pericarditis suggest that constriction is rarely the only cause of cardiac failure.

Another study reported similar findings, with radiation-induced constriction leading to significantly decreased 10-year survival after pericardiectomy.³⁷ The authors also noted that patients who underwent pericardiectomy for radiation-induced constriction had demonstrably worse late functional status. Fifteen of 17 long-term survivors with a history of previous radiation therapy showed New York Heart Association class III or IV symptoms, whereas only 31 of 112 patients without a history of radiation therapy had major symptoms of heart failure.

Financial Disclosures: None Reported.

13 DECORTICATION AND PLEURECTOMY

Eric S. Lambright, M.D.

In normal circumstances, the pleural space is a potential cavity between the lung and the chest wall—more specifically, between the visceral pleura and the parietal pleura. In the average healthy patient, this space is less than 1 mm thick. There are a number of pathologic processes that can alter the transport of cells and fluid within this space and thus give rise to clinically significant sequelae. One such process is fibrothorax, which is defined as the presence of abnormal fibrous tissue within the pleural space, resulting in entrapment of the underlying pulmonary parenchyma (a state variously referred to as trapped lung, restrictive pleurisy, or encased lung). Decortication is the surgical procedure by which this restrictive fibrous layer is peeled away from the lung; the literal meaning of the term is the stripping away of a rind (from the Latin word *cortex* “bark, rind, shell”). The technical goals of the operation are to reexpand the lung and resolve the pathologic process affecting the pleural space so that pulmonary function and chest wall mechanics will improve and the patient’s symptoms will be relieved.

Successful management of a patient with fibrothorax depends on close adherence to basic surgical tenets: appropriate selection of patients for surgical treatment, preoperative optimization of the patient’s physiologic status, exacting attention to the technical aspects of the procedure, and timely intervention to address perioperative complications. If insufficient attention is paid to any of these important tenets, decortication may fail to achieve any significant improvement in the patient’s symptoms or physiologic status, potentially leaving him or her in an even more debilitated state.

Preoperative Evaluation

PATHOPHYSIOLOGY OF FIBROTHORAX

Although any insult to the pleura can result in an inflammatory response with fibrin deposition,¹ hemothorax and infection (bacterial and mycobacterial) remain the most common causes of fibrothorax [see Table 1]. Typically, empyemas evolve over a 4- to 6-week period as the infection progresses throughout the pleural space. The first (exudative) phase is characterized by a thin, fibrin-containing fluid exudate. The second (fibropurulent) phase is characterized by a heavy fibrin deposit over the pleural surface with the development of loculations and fibrous debris in the thoracic cavity. The third (organizational) phase, which begins at about 3 to 5 weeks, is characterized by the formation of a thick fibrous peel that imprisons the lung and prevents expansion. When fully developed, this peel has three distinct layers: (1) an outer layer consisting of loosely organized vascular tissue, (2) a middle layer consisting of fibrous connective tissue that is relatively avascular and acellular, and (3) an inner layer consisting of necrotic tissue and fibrinoid masses.² Generally, if a hemothorax is small, it will be reabsorbed, provided that the lymphatic system is intact. However, if the hemothorax is relatively large, if there is continued bleeding, or if bacteria are present, there is a high likelihood that a fibrous peel will eventually form.³

HISTORY AND PHYSICAL EXAMINATION

The physiologic consequences of a fibrothorax culminate in pulmonary restriction, manifested by decreased lung volumes, reduced diffusion capacity, and lower expiratory flow rates. Movement of the chest is impaired.⁴ The initial clinical presentation of a fibrothorax depends on its cause and severity, as well as on the presence or absence of underlying parenchymal disease. Typically, dyspnea on exertion is the most common presenting symptom, though cough, fever, pleuritic chest discomfort, malaise, night sweats, weight loss, or chest pressure may also be present. In obtaining the clinical history, it is important to determine whether the condition is chronic and whether there are any other underlying disease processes that may be complicating the pulmonary disease process. Physical examination yields relatively nonspecific findings; typically, decreased breath sounds and decreased chest wall excursion are noted.

DIAGNOSTIC IMAGING AND PHYSIOLOGIC TESTING

Radiographic evaluation is the mainstay of diagnosis [see Figures 1, 2, and 3]. Computed tomography (CT) of the chest is the imaging modality of choice for delineating abnormalities of the pleural space and defining the character of the pleural disease process. CT scanning can assess the extent and thickness of pleural involvement and characterize associated parenchymal disease. It readily identifies parenchymal abnormalities such as fibrosis, bronchiectasis, and malignancy. Such factors play a role in surgical decision making. In particular, malignancy must be included in the differential diagnosis of fibrothorax and ruled out; the management options for malignant disease are quite different from those for benign disease.

Physiologic testing with spirometry and evaluation of diffusing capacity helps define the degree of pulmonary dysfunction and facilitates risk stratification. The results of pulmonary function testing may be quite abnormal preoperatively and are often worse than would have been expected from the radiographic evaluation. Marked abnormalities in physiologic testing should not be considered absolute contraindications to surgical intervention, because some degree of improvement may be anticipated. The improvement in dyspnea, pulmonary reexpansion, and parenchymal function that can realistically be expected after decortication may be

Treatments included three courses of antibiotics and bronchodilator therapy. (b) A chest CT scan from the same patient shows a large pleural collection containing air and demonstrates pleural thickening (arrow). The findings are consistent with empyema. Thoracentesis was performed, demonstrating white, creamy purulence but failing to achieve reexpansion of the lung. Decortication was performed.

estimated on the basis of the preoperative diagnostic imaging and physiologic testing. Ultimately, the surgeon's judgment plays the key role in deciding for or against surgical intervention.

EXCLUSION OF MALIGNANCY

In the evaluation of a patient with a fibrothorax, it is essential to keep in mind the possibility of a malignant pleural process. If malignancy is a concern, this possibility should be excluded before a decision is made to proceed with decortication. Decortication of a malignant fibrous peel is difficult, and the outcome is not particularly satisfying from the standpoint of lung expansion; accordingly, for a pleural malignancy, a lesser, palliative intervention is generally more appropriate than decortication. Metastatic involve-

ment of the pleura (usually by adenocarcinoma) is far more common than malignant pleural mesothelioma, which is a primary malignancy of the pleural space. Cytologic evaluation of the pleural fluid will establish the diagnosis of metastatic pleural involvement in most cases; however, it tends to be less effective in establishing the diagnosis of malignant mesothelioma. If the presentation of a chronic pleural process is atypical and the etiology is poorly defined, a degree of suspicion for malignancy must be maintained. Appropriate initial pleural biopsies can be useful for ruling out underlying malignancy before decortication. Currently, pleural biopsy is usually performed by means of video thoracoscopy, but closed pleural biopsy is still done occasionally (though it is fast becoming a lost art). If a malignancy is identified, therapeutic alter-

Figure 2 (a) Shown is a preoperative chest CT scan from a patient with a 6-week history of malaise and weight loss who ultimately presented with hypotension and respiratory insufficiency necessitating mechanical ventilatory support. (b) A chest CT scan obtained from the same patient after decortication shows complete reexpansion of the lung.

Figure 3 Shown is a chest CT scan from a patient with a pulmonary abscess (arrow) complicated by pleural space infection. The pleural space was drained via a chest tube thoracostomy. The lung did not completely reexpand. Sepsis was controlled with antibiotics. Decortication was not considered, because of the extensiveness of the underlying pulmonary parenchymal process.

natives such as pleurodesis or use of the Pleurx pleural catheter (Denver Biomedical, Golden, Colorado) may be indicated.

Operative Planning

INDICATIONS FOR SURGICAL INTERVENTION

Fibrothorax is a potentially preventable complication. As noted (see above), it is a manifestation of a chronic disease process; thus, the earlier a therapeutic intervention is initiated, the better the chances that fibrothorax can be prevented. In patients with a traumatic hemothorax, early and complete drainage often serves to prevent fibrothorax.⁵ Observational studies have consistently demonstrated that early evacuation of a clotted hemothorax reduces morbidity and mortality and prevents empyema.^{6,7} When parapneumonic effusions are thin, simple aspiration or chest tube drainage may suffice. Often, the fibropurulent stage characterized by loculated empyema or clotted hemothorax can be successfully managed by means of thoracoscopic intervention with debridement of the intrathoracic debris and irrigation; this approach allows the parenchyma to reexpand before a restrictive peel can be formed.⁸

The primary indication for decortication in a patient with fibrothorax is symptomatic pulmonary restriction resulting from the development of a fibrinous peel. The timing of the operation is an important consideration. In many cases, pleuropulmonary processes are self-limiting, and the symptoms resolve over time. As a rule, decortication should be considered (1) if pleural thickening has been present for a substantial period (> 4 to 6 weeks), (2) if respiratory symptoms remain disabling, and (3) if there is radiographic evidence of reversible entrapment of the lung. Decortication is often necessary when lesser interventions have not achieved control of a pleural space infection or have not enabled the lung to reexpand. For tuberculous empyema, drug therapy remains the treatment of choice. Decortication may also be performed to treat pleural effusions that persist despite long-term medical therapy.

A condition that poses a major challenge to the thoracic surgeon is pleural space infection with underlying parenchymal dis-

ease or airway stenosis.^{9,10} In this setting, decortication is destined to fail: the lung parenchyma will not reexpand to fill the pleural space completely, and any surgical intervention carried out on the diseased lung will only aggravate the underlying disease process. Pleuropneumonectomy may be the only option, though it should be considered a last resort, to be used only if there is significant parenchymal destruction. Decortication may be precluded by invasive uncontrolled pulmonary infection, contralateral pulmonary disease, or a chronically debilitated state that results in a significant or even prohibitive level of operative risk. Medical optimization may be required as an initial step. Often, however, the underlying pleural infection process remains unresolved despite optimal medical management, and surgical intervention becomes necessary in a patient who remains medically fragile. Optimally, the patient's nutritional status should be normalized (with forced feedings, if necessary), and sepsis, if present, should be controlled with appropriate antibiotic therapy.

TECHNICAL CONSIDERATIONS

Essentially, pleural cavity infection and fibrosis are problems of residual intrapleural space. The lung cannot expand sufficiently to fill the hemithorax, and as a consequence, the residual space becomes or remains infected. These problems often prove difficult for the thoracic surgeon to address; good surgical judgment is crucial for ensuring optimal outcomes. In planning for decortication, there are a number of technical issues that must be considered, including the timing of intervention (taking into account whether the disease process is chronic or subacute), the quality of the underlying pulmonary parenchyma, the expected ability of the lung to reexpand, the possible need to address residual space issues, and the physiologic status of the patient. The goal of the procedure is to remove the peel from the visceral pleura so as to allow the lung to reexpand and, equally important, to ensure that any potential residual space is obliterated.¹¹

There are few absolute contraindications to pulmonary decortication, other than a patient who is unfit to undergo surgery or the presence of underlying parenchymal or bronchial disease that would prevent lung reexpansion. There are, however, some situations in which a lesser intervention (e.g., chest tube thoracostomy, rib resection, or open window thoracostomy) might yield a better outcome than decortication would from the patient's perspective. In general, decortication is not required for a small, well-defined residual cavity; it is usually reserved for a diffuse pleural process. Whether the disease process is chronic or subacute will also influence the surgeon's choice of approach. For example, in the earlier stages of pleural space infection, when the peel is less organized, a thoracoscopic approach that includes cleansing of the pleural space, removal of the pleural debris, and breaking up of loculations may prove adequate. With a chronic process, however, an attempt at thoracoscopic decortication may do more harm than good.

Operative Technique

The first step in open decortication (which at times includes parietal pleurectomy in addition to decortication) is bronchoscopic evaluation aimed at identifying any endobronchial obstructions that might prevent satisfactory lung expansion. Such evaluation sometimes yields unexpected findings, such as malignancy, bronchial stenosis, or a broncholith.

The chest is entered at the appropriate predetermined interspace (usually the fifth or sixth) via a standard posterolateral thoracotomy [see Figure 4]; alternatively, a vertical axillary thoracotomy may be employed. With either approach, the latissimus dorsi

Figure 4 Decortication. The chest is entered through a posterolateral thoracotomy at the fifth or sixth interspace.

and the serratus anterior should be spared because either or both might subsequently be required for a transposition muscle flap. Because the chest is often rigid and contracted as a result of the underlying inflammatory process, it may be helpful to resect a rib in a subperiosteal fashion. This measure facilitates exposure and helps define the extrapleural plane for the initiation of parietal pleurectomy.

When the disease process is chronic (i.e., has lasted longer than 6 weeks), the parietal pleura and the visceral pleura are often fused. In this situation, one would proceed with pleurectomy. When adhesions are present between the pleural layers but the visceral pleura has not fused with the parietal pleura [see Figure 5], the adhesions may be lysed with a combination of sharp dissection and electrocauterization.

The key to a technically successful decortication is to define the correct plane between the pleural peel and the visceral pleura. If the pleural resection is inadequate, lung expansion will be compromised. If the pleurectomy is too deep, parenchymal injury will result, bleeding and air leakage will occur, and postoperative recovery will be prolonged. Gentle manual ventilation of the lung

operated on, coupled with continuous positive airway pressure (CPAP), should provide appropriate countertraction from the underlying lung parenchyma.

An incision is made in the pleural peel, and the appropriate decortication plane is identified [see Figure 6a]. The pleural peel is then grasped with hemostats, and blunt and sharp dissection is carried out over a broad area to separate the peel from the visceral pleura [see Figure 6b]; a sponge-ball or peanut dissector may be useful for this purpose. Care must be taken to keep from injuring the underlying pulmonary parenchyma, which is fragile; inadvertent injury may result in prolonged and unnecessary air leaks. Some degree of patience is required, in that this operation often becomes tedious. For an optimal surgical outcome, all portions of the lung encased by the peel should be addressed. To this end, it is often necessary to follow the peel into the fissure, down onto the diaphragm, and into the posterior and anterior sulci. At times, a second entry point into the chest through another interspace may be required to achieve an optimal technical result. Should better exposure be deemed necessary, one should not hesitate to proceed with this counterincision.

Figure 5 Decortication. Any adhesions between the visceral pleura and the parietal pleura are lysed with a combination of sharp dissection and electrocauterization.

Figure 6 Decortication. (a) With the lung expanded, the pleural peel is sharply incised, and the appropriate decortication plane is identified. (b) The peel is separated from the visceral pleura with blunt and sharp dissection.

Once resected, the peel is sent for pathologic and microbiologic evaluation. The lung is tested to confirm that it is capable of complete reexpansion. Any large parenchymal air leaks that are noted may be oversewn, but this step often is not necessary. The various pulmonary parenchymal sealants now commercially available may reasonably be considered for control of parenchymal air-leaks. Chest tubes are placed—typically, one along the diaphragm, a second anteriorly, and a third posteriorly, toward the apex. Provided that the lung is satisfactorily reexpanded, air leaks will seal promptly. Hemostasis must be ensured: a residual hemothorax in a patient with a pleural space infection will serve as a nidus for ongoing infection.

The role of parietal pleurectomy in this setting remains unclear. Opinions differ, but objective data are sparse. Parietal pleurectomy does result in some improvement of the mechanics of the thoracic cage¹²; however, it also increases the risk of bleeding, prolongs the procedure, and places vital intrathoracic structures (e.g., the phrenic and vagus nerves, the esophagus, the brachial plexus, and certain blood vessels) at risk for injury. In addition, it is often possible that the pleural process will resolve without parietal pleurectomy once the underlying issues are addressed. The technically optimal strategy may be to adopt a compromise approach—that is, to perform a partial parietal pleurectomy and to take extra care when dissecting near the vital mediastinal structures.

Postoperative management of the chest tube is dictated by culture results, intraoperative findings, and the patient's clinical sta-

tus. Concerns related to residual space may be managed by means of open tube thoracostomy, open window thoracostomy, or placement of a muscle flap. On rare occasions, thoracoplasty with multiple rib resection may be considered to obliterate any infection in the residual space by bringing the chest wall down to fill the space.

Outcome Evaluation

The morbidity and mortality to be expected after decortication depend on the severity of the underlying illness and on the occurrence of perioperative complications. In a review from 1985, mortality was less than 8%.¹³ Complications tend to be either infection related (e.g., perioperative sepsis syndrome) or technique related (e.g., bronchopleural fistula, hemorrhage, and persistent air leakage); some of them may necessitate additional surgical intervention. As with all operations in the chest, close attention to detail and meticulous surgical technique are critical for minimizing the incidence of postoperative complications.

The degree of functional improvement attained after decortication depends primarily on the presence and extent of disease in the underlying lung parenchyma.¹⁴⁻¹⁶ If the parenchyma of the lung is normal, complete reexpansion of the lung and obliteration of the pleural space should be achievable. Lung volumes usually improve measurably after decortication, but they generally do not return to normal.^{14,17} Changes within the chest (i.e., mediastinal shift and elevation of the diaphragm, with a resultant decrease in

Table 2 Causes of Failed Decortication

Underlying parenchymal disease	Active tuberculosis or invasive pulmonary infection Bronchial stenosis Chronic lung collapse
Technical considerations	Residual space Inadequate lung expansion Air leakage Postoperative hemothorax

the size of the thorax) may account for this finding. It is unclear to what extent the expected functional improvement is influenced by whether the pleural process is acute or chronic. Some authors have observed an association between shorter durations of pleural disease before treatment and improved outcomes^{18,19}; others have not observed such an association.¹⁴ Failure to achieve improvement after decortication appears to be most strongly related to errors of surgical judgment (in particular, poor patient selection) and to insufficiently meticulous surgical technique (leading to perioperative complications).

Although to date, no studies have dealt specifically with failure after decortication, it is likely that technical difficulties are the most common cause of such failure, with the main problem being inadequate obliteration of the pleural space [see Table 2].

Inability to define the plane of dissection between the peel and the visceral pleura is an especially troublesome technical challenge that can adversely affect results. If visceral pleurectomy is performed, air leakage and postoperative hemorrhage may compromise pulmonary function. Care must be taken throughout the operation to protect the phrenic nerve from injury; fortunately, this usually is not an issue, because the mediastinal pleura is rarely involved in the inflammatory process. Incomplete parietal pleurectomy or inability to free the diaphragm may also compromise results.

If patients are appropriately selected, complete reexpansion of the lung after decortication can usually be achieved. Occasionally, however, an issue related to residual pleural space may arise after an otherwise technically satisfactory decortication. If this space is not obliterated, failure is inevitable. Options for addressing the residual space problem include thoracoplasty and tissue transposition. Either the latissimus dorsi or the abdominal omentum will provide sufficient bulk for obliteration of the residual space.^{20,21} The omentum is preferable when the space is in the inferior hemithorax, whereas the latissimus dorsi is preferable when the space is in the superior hemithorax. At the time of the initial incision, the surgeon should keep in mind the possibility that tissue transposition may eventually prove necessary and should therefore opt for a muscle-sparing thoracotomy if possible.

At present, the use of thoracoscopy to address fibrothorax definitively cannot be recommended.

14 PULMONARY RESECTION

Min P. Kim, MD, and Ara Vaporciyan, MD, FACS

Anatomic resections of the lung (including pneumonectomy and lobectomy) are the standard operative techniques employed to treat both neoplastic and nonneoplastic diseases of the lung. In neoplastic disease of the lung the disease process can be divided between primary and metastatic lung cancers. In patients with primary lung cancer, the staging of the patient is critical to provide best therapy for the patient. There is no role of pulmonary resection for patients with metastatic disease or stage IV disease. In terms of the nodal stations, pulmonary resection maybe offered in patients with N1 disease or metastatic cancer to ipsilateral hilar lymph nodes (level 10, 11, 12, 13, 14). There is controversy about the role of pulmonary resection in patients with N2 disease or metastatic cancer to ipsilateral mediastinal lymph nodes (on right: level 2R, 4R, 7 and on left: level 2L, 4L, 5, 6, 7). The options include either induction chemotherapy followed by surgery then consolidative radiation to the mediastinum, induction chemoradiotherapy followed by surgery, or chemoradiation therapy without surgery. The final option is most commonly chosen when multiple N2 lymph nodes are involved, the nodal disease is bulky and deemed unresectable, or when the surgical risk is felt to be too high (for example when a right pneumonectomy is required). Finally, there is no role for pulmonary resection in patients with N3 disease or metastatic cancer to contralateral mediastinal lymph nodes. In patients with no nodal or metastatic disease, pulmonary resection is a primary therapy. Any surgeon who intends to operate on the pulmonary system must be keenly aware of the anatomy of the pulmonary vasculature and the bronchi and the relation between the two. There is no substitute for this degree of familiarity. Detailed discussions are available in existing anatomy textbooks. In what follows, we describe several of the more common techniques employed for anatomic resections of the lung.

Preoperative Evaluation

Detailed discussion of the physiologic evaluation of the patient and of the indications for lobectomy or pneumonectomy is beyond the scope of this chapter. In general, the patient must have sufficient pulmonary reserve to tolerate the planned resection. A common contraindication for surgery is an estimated postresectional forced expiratory volume in 1 second (FEV₁) and carbon monoxide diffusion capacity (DLCO) of less than 35 to 40%. The choice of what volume of lung to resect for lung cancer should be a balance between achieving an adequate oncologic outcome and preservation of pulmonary

function. When wedge resection was compared with lobectomy for tumors smaller than 3 cm there was a higher local recurrence rate after a wedge resection compared with a lobectomy. Based on these data the current recommendation is to perform a lobectomy if the patient's pulmonary status will tolerate that volume of resection. A minimally invasive lobectomy can be substituted for an open lobectomy although the presence of hilar nodal involvement by tumor or granulomatous disease is a relative contraindication to this procedure. For metastatic tumors and diagnostic resections of pulmonary nodules a wedge resection, if feasible, is considered adequate. In addition, it is essential to carry out a thorough evaluation of all other systems, especially the cardiac system. In patients who have received preoperative chemotherapy, the hematologic and renal systems should receive particular attention.

Operative Planning

ANESTHESIA

Although pulmonary resections can be performed with bilateral lung ventilation, careful hilar dissection is greatly facilitated by using unilateral lung ventilation. The advent of double-lumen endotracheal tubes and bronchial blockers has made it possible to isolate the ipsilateral lung and has made it easier for surgeons to carry out complex hilar dissections with the required precision. In patients with centrally located tumors, care must be taken with tube placement: inadvertent trauma to an endobronchial tumor during placement of a double-lumen tube can lead to significant bleeding and compromise of the airway. Bronchoscopic confirmation of tube position is recommended after the patient has been positioned.

Requirements for monitoring and intravenous access are determined by the patient's preoperative status and by the complexity of the resection. In most cases, the standard practice is to place a radial arterial catheter, two large-bore peripheral intravenous catheters, and a Foley catheter, with more invasive monitoring employed if mandated by the patient's clinical condition. Thoracic epidural catheters are also commonly employed for postoperative pain control. If carefully placed by an experienced anesthesiologist, these catheters can remain in place for as long as 7 days or until the chest tubes are removed.

PATIENT POSITIONING

Patients are routinely placed in the lateral decubitus position, with the table flexed just cephalad to the superior iliac

crest. This positioning allows sufficient access for most incisions. If an anterior thoracotomy or a sternotomy is planned, the patient may be placed in the supine position, with a pillow placed in such a way as to elevate the area of the thorax that will be operated on.

When the patient is in the lateral decubitus position, several measures should be adopted to guard against injury. Adequate padding should be employed to prevent the development of pressure points on the contralateral lower extremity. A low axillary roll should be used to prevent injury to the contralateral brachial plexus and shoulder girdle. Finally, adequate padding should be placed beneath the head to keep the cervical spine in a neutral position.

GENERAL TECHNICAL CONSIDERATIONS

Incisions

Posterior lateral thoracotomy remains the standard incision for anatomic pulmonary resections; however, safe and complete resections can also be performed through a variety of smaller incisions, including posterior muscle-sparing, anterior muscle-sparing, and axillary thoracotomies. In most cases, the thorax is entered at the fifth intercostal space, an approach that affords excellent exposure of the hilar structures. The anterior muscle-sparing thoracotomy is generally placed at the fourth intercostal space because of the more caudal positioning of the anterior aspects of the ribs. Although a sternotomy may be employed to gain access to the upper lobes, it does not provide good exposure of the lower lobes and the bronchi.

Thoracoscopic lobectomy [see 4:10 *Video-Assisted Thoracic Surgery*] is being performed with increasing frequency, especially for early-stage lesions. This procedure employs two or three 1 cm ports and a utility thoracotomy (frequently in the axillary position) for instrumentation and removal of the specimen. Rib spreading is not necessary, because visualization is achieved via the thoracoscope. The various thoracoscopic lobar resections are generally similar with regard to isolation and division of the hilar vessels and bronchi. Complete nodal dissections are also performed thoracoscopically. The main advantages of this approach seem to be reduced postoperative pain and earlier return to normal activity, but to date, no randomized trials have shown these advantages to be significant. Because of the technical challenges posed by thoracoscopic pulmonary resections, surgeons should have a complete mastery of the hilar anatomy before attempting these procedures.

Special Intraoperative Issues

Upon entry into the thoracic cavity, all benign-appearing filmy adhesions should be mobilized. Any malignant-appearing, broad-based, or dense adhesions should be noted, and a decision whether to perform an extrapleural dissection or a chest wall resection should be made on the basis of the depth of involvement and the preoperative imaging studies. If there is reason to believe that the chest wall or the parietal pleura may be involved, a more aggressive approach may be required to achieve a complete resection. These techniques are beyond the scope of this chapter.

Once the lung is freed of all adhesions, the inferior pulmonary ligament is divided and the lung rendered completely atelectatic. The entire lung and the parietal pleura are

inspected and palpated. In patients with malignant disease, biopsies of any suspicious nodules are performed. The presence or absence of pleural fluid should be noted; if fluid is present, it should be aspirated and sent for immediate cytologic analysis.

Frequently, the fissures are incomplete as a consequence of congenital absence, inflammatory disease, or a neoplasm. If the adhesions within the fissure are filmy, they may be divided sharply or with the electrocautery while the lung is being ventilated. If the adhesions are more densely adherent, the fissures may have to be completed with staplers. During resection for malignancy, any evidence of tumor extension across a fissure or of hilar nodal involvement should be noted. A decision is then made regarding the extent of the required resection. If there is only minor extension, wedge resection of a portion of the additional lobe is indicated. If, however, the involvement is significant, segmentectomy, bilobectomy, or pneumonectomy may be indicated. Often we develop the fissures during ventilation until a dense or incomplete region is encountered, at which point we complete the remainder of the fissure with staples. For this approach to work, the vascular and bronchial anatomy must already have been completely delineated. If the vascular structures cannot be identified in the fissure because the fissure is fused, the pulmonary artery branches will have to be approached from the anterior and posterior hilum.

Traditionally, during a lobectomy, the arterial branches are divided first, followed by the venous branches. However, if conditions exist that limit exposure (e.g., a centrally placed tumor or significant inflammation and scarring), the surgeon should start with the structures that provide the most accessible targets. Veins may be ligated first. Proponents of this approach believe that it may limit the escape of circulating tumor cells (an event that rarely, if ever, occurs); opponents claim that initial vein ligation may lead to venous congestion and retention of blood that is subsequently lost with the specimen, although peribronchial venous channels will frequently prevent this result. The bronchus may also be ligated first. However, two points should be kept in mind if this is done. First, the distal limb of the bronchus (the specimen side) should be oversewn to prevent drainage of mucus into the chest. Second, after division of the bronchus, the lobe is much more mobile; therefore, to prevent avulsion of the pulmonary artery branches, care should be taken not to employ excessive torsion or traction.

The techniques used for dissection, ligation, and division of pulmonary arteries and their branches differ from those used for other vessels. Pulmonary vessels are low-pressure, high-flow, thin-walled, fragile structures. Accordingly, for rapid and safe dissection, a perivascular plane, known as the plane of Leriche, should be sought. This plane may be absent in the presence of long-standing granulomatous or tuberculous disease, after major chemotherapy, after thoracic radiotherapy, and in cases of reoperation. In these situations, proximal control of the main pulmonary artery and the two pulmonary veins may be necessary before the more peripheral arterial dissection can be started. Before any pulmonary vessel is divided, it should be controlled either with two separate suture ligatures proximal to the line of division or with vascular staples; stapling devices are especially useful for larger vessels.

Exposure of the bronchus should not involve stripping the bronchial surface of its adventitia. Aggressive dissection may compromise the vascular supply and lead to impaired healing and bronchial dehiscence. Overlying nodal tissues should be cleared, and major bronchial arteries should be clipped just proximal to the point of division. Bronchial closure has been greatly facilitated by the use of automatic staplers. Because the bronchus is frequently the last structure to be divided before removal of the specimen, we often apply staples only to the proximal side of the bronchus and divide the bronchus distal to the staple line. Once the stapler is applied, every effort should be made to minimize its movement during firing so as to prevent injury to the remaining proximal bronchial segment. With the stapler applied but not yet fired, the remaining lung should be ventilated to determine whether there is any impairment of ventilation secondary to placement of the stapler too close to a proximal lobar bronchus. Only when the absence of ventilatory impairment has been confirmed should the stapler be fired. When bronchial length is limited, one may perform suture closure of the bronchial stump rather than attempt to force a stapler around the bronchus. Whenever there is a high risk of bronchial stump dehiscence (e.g., after chemotherapy, radiotherapy, or chemoradiotherapy; in patients for whom adjuvant therapy is planned; or after right pneumonectomy), a vascularized rotational tissue flap (e.g., from the pericardium, the pericardial fat pad, or intercostal muscle) should be used to reinforce the bronchial closure.

Closure and Drainage

Once the bronchial closure is complete, the next step is to test its adequacy. The bronchial stump is submerged under normal saline, and the lung is inflated to a tracheal pressure of 45 cm H₂O. Any area of hilar dissection and divided fissures should be evaluated in a similar fashion. Significant parenchymal air leaks should be repaired with interrupted fine sutures (e.g., 4-0 polypropylene). If the air leak is from a diffuse raw surface, especially after upper lobectomy, construction of a pleural tent should be considered. Any air leak from the bronchial stump should be assessed very carefully. A simple repair with fine absorbable sutures may suffice, or the entire closure may have to be redone. Strong consideration should be given to reinforcing the stump with vascularized tissue (see above).

The chest is usually drained with two chest tubes that are positioned anteriorly and posteriorly and exit through separate stab incisions in the chest wall. If an epidural or a paravertebral catheter is being employed for postoperative pain management, the chest tubes should exit through an intercostal space that is no more than two spaces below the intercostal space used for entry into the chest. Failure to follow this recommendation is likely to result in pain originating from the chest tube site that will not be adequately addressed postoperatively and will lead to a significant increase in discomfort.

After a pneumonectomy, the chest tubes can be omitted. If this option is chosen, a needle should be used to aspirate 1,000 to 1,200 mL of air from the hemithorax operated on after closure of the skin. If a chest tube is used, a balanced drainage system is employed without suction. At most institutions, suction is employed postoperatively for all other

resections (i.e., lobectomy, segmentectomy, and wedge resection); however, careful use of water seal in selected patients (i.e., those with small air leaks whose lungs do not collapse while on water seal) may allow earlier withdrawal of the tube.

Operative Technique

INITIAL STEPS

After making a posterior lateral thoracotomy and exposing the chest cavity through the fifth intercostal space, the inferior pulmonary ligament is taken down and the hilum is mobilized. A lung grasper is used to provide tension on the lower lobe, and the inferior pulmonary ligament is taken down using a cautery or bluntly to the inferior pulmonary vein. One needs to be very careful not to injure the pulmonary vein. After this is done, the lung is freed of any filmy pleural attachments. Dense attachments may indicate chest wall involvement and should be approached as such.

RIGHT LUNG

Right Hilar Dissection

In the right thoracic cavity, it is important to identify the inferior pulmonary vein draining the right lower lobe, superior pulmonary vein draining the right upper and right middle lobe, the main pulmonary artery, and the truncus anterior branch of the pulmonary artery. In addition, the right main bronchus and the right upper-lobe takeoff and the right bronchus intermedius should be identified. Then the lung is rotated posteriorly, and the pleura is incised posterior to the course of the phrenic nerve, which usually passes close to the base of the superior pulmonary vein. The phrenic nerve is carefully and gently mobilized anteriorly, avoiding the use of cautery. This will expose the superior pulmonary vein and inferior pulmonary vein. The right upper lobe is then rotated more inferiorly to provide a better view of the superior aspect of the hilum. This step allows complete exposure of the truncus anterior branch of the pulmonary artery. Finally, the lung is rotated anteriorly, and the right main bronchus as well as the right upper-lobe bronchus and the bronchus intermedius are exposed.

Right Upper Lobectomy

Pulmonary arteries: truncus anterior and posterior ascending Two branches of the pulmonary artery go into the right upper lobe: the truncus anterior and posterior ascending arteries. The truncus anterior is the first branch coming off the main pulmonary artery and, most of the time, is a large branch that immediately bifurcates to two arteries; however, at times two truncus anterior arteries may be coming off the pulmonary artery. It is imperative that dissection be performed with care. Once the vessel is exposed, it is either suture-ligated and divided or transected with an endovascular stapler.

It is very important to accurately identify all the vessels to prevent inadvertent ligation of the wrong artery. To expose the posterior ascending pulmonary artery, the dissection begins within the interlobar fissure, and the pulmonary artery is exposed at the junction of the major and minor fissures [see *Figure 1*]. In many cases, the artery is partially obscured by a level 11 interlobar lymph node, which should be removed. Also

Figure 1 Right upper lobectomy. Shown is the surgeon's view of the right interlobar fissure. The fissures have been completed, and the segmental arteries to the upper, middle, and lower lobes have been identified. The posterior ascending branch to the upper lobe most commonly varies with respect to size and origin. This vessel may be absent or diminutive and may arise from the superior segmental branch to the lower lobe. The posterior segmental vein draining into the superior pulmonary vein (not seen) is clearly visualized in the right upper lobe, lateral to the pulmonary artery branches.

present is the posterior segmental branch of the superior pulmonary vein, which traverses the fissure in a posterior-to-anterior direction. The pulmonary artery lies medial and inferior to this venous branch. Once the pulmonary artery is identified, the branches within the fissure are exposed, including the posterior ascending artery to the right upper lobe. The posterior ascending artery typically comes off the main pulmonary artery opposite to the right middle-lobe pulmonary artery. However, at times there may be no posterior ascending artery or there may be two posterior ascending arteries, or the posterior ascending artery may originate as a branch of the superior segment artery to the right lower lobe. Distal to the posterior ascending artery is the superior segmental artery to the right lower lobe and the basilar branches to the right lower lobe. If the exposure is adequate, the posterior ascending branch can be ligated and divided.

Fissure between the right lower lobe and the right upper lobe If additional length is required to expose the posterior ascending artery, the fissure between the superior segment of the lower lobe and the posterior segment of the upper lobe can be completed. This is accomplished by open-

ing the pleura in the posterior hilum along the lateral edge of the bronchus intermedius. A level 11 lymph node will be encountered between the right upper-lobe bronchus and the bronchus intermedius. Removal of this interlobar node (sometimes referred to as the "sump node") will expose the posterior ascending branch of the pulmonary artery. A right-angle clamp can be passed from the interlobar fissure between the superior segmental branch of the pulmonary artery and the posterior ascending pulmonary artery to the opening between the right upper-lobe bronchus and the bronchus intermedius. A silk can be placed through this opening, which will guide in separation of the right upper lobe and the right lower lobe. The fissure can be completed with gastrointestinal anastomosis (GIA) staplers. The posterior ascending artery can be ligated and divided after completion of the fissure.

Pulmonary vein: right upper-lobe branch of the superior pulmonary vein The superior pulmonary vein is dissected, and the apical, anterior, and posterior branches are encircled [see Figure 2]. Care is taken to preserve the middle-lobe branches. Both the right upper lobe and the middle lobe often drain into the superior pulmonary vein. However, at times the right middle lobe may drain into the inferior pulmonary vein or into both the superior and the inferior pulmonary vein. The right middle-lobe pulmonary vein branch has to be clearly identified prior to taking the right upper-lobe pulmonary vein branches. The branches draining the upper lobe are then ligated and divided or controlled with a vascular stapler. Division of the veins before division of the arterial supply will not cause the lobe to become engorged. Instead, through collateral venous drainage to the middle lobe or via bronchial venous channels, blood will be shunted away from the upper lobe.

Fissure between the right upper lobe and the right middle lobe After the division of the right upper-lobe pulmonary veins, the interlobar (or truncus posterior) branch of the right pulmonary artery will be visible as it courses posterior to the superior pulmonary vein branches. Dissection continues along the lateral surface of the interlobar artery. Once the branches to the middle-lobe artery are identified, the dissection should reach the region previously dissected within the fissure. A right-angle clamp can be used to pass a silk along this opening and keep the right middle pulmonary artery and vein with the right middle lobe. The fissure between the middle lobe and the upper lobe can now be completed through serial application of GIA staplers.

Right upper-lobe bronchus The upper lobe is retracted superiorly and posteriorly, and the interlobar artery is gently retracted anteriorly. The bronchus to the right upper lobe is circumferentially exposed, and all nodal tissue surrounding the right upper-lobe bronchus is swept distally so that it can be included with the specimen. Every effort is made to avoid devascularizing the bronchus. Once an adequate length of the right upper-lobe bronchus is exposed, the lung is rotated anteriorly to allow visualization of the course of the bronchus intermedius. The bronchus is ligated with a transverse anastomosis (TA)-30 stapler loaded with 4.8 mm staples. Care is taken to achieve close apposition of the anterior wall to the posterior membranous wall of the bronchus. With the stapler applied but not fired, the right lung is ventilated to confirm that the bronchus intermedius has not been compromised. The stapler is fired, the bronchus is divided, and the specimen is removed.

To prevent middle-lobe syndrome resulting from torsion of the narrow hilum of the middle lobe after an upper lobectomy, the middle lobe should be secured to the lower lobe. Once the lungs are reexpanded, a small portion of the lower lobe and a comparable portion of the middle lobe are grasped along the major fissure. A single application (or, at most, two applications) of a TA stapler should suffice to secure the lobes to each other at this site and thus prevent middle-lobe torsion.

Right Middle Lobectomy

Pulmonary arteries: one or two right middle-lobe pulmonary arteries The initial steps in a right middle lobectomy are similar to those in a right upper lobectomy. The pulmonary artery and its branches are identified within the fissure. The middle-lobe artery is identified [see Figure 1]. Not infrequently, there are two middle-lobe arteries. When this is the case, the most proximal branch is commonly located across from the posterior ascending branch to the right upper lobe. Once the anatomy has been confirmed, the arterial branches to the middle lobe can be individually ligated and divided. If additional exposure is needed before ligation, the fissures can be completed to yield added exposure of a proximal middle-lobe artery.

Pulmonary vein: right middle-lobe branch of the superior pulmonary vein Once the arteries are divided (or if additional exposure is required), the lung is rotated

posteriorly to expose the superior pulmonary vein [see Figure 2]. The branches to the middle lobe are carefully identified, doubly ligated, and divided. The posterior segmental branch of the superior pulmonary vein should now be easily identifiable, originating just cephalad to the middle-lobe vein and coursing posteriorly (lateral to the interlobar artery) to drain the posterior segment of the right upper lobe. As noted (see above), this venous branch is easily identified during dissection of the interlobar artery within the fissure.

Fissure between the right upper and middle lobes and fissure between the right middle and lower lobes To complete the fissure between the upper and middle lobes, dissection continues along the caudal and lateral surface of the posterior segmental venous branch until the previously performed dissection of the interlobar artery within the fissure is reached. The fissure is then completed through serial application of GIA staplers. When the fissure is complete, the surgeon has a clear view of the posterior segmental branch of the superior pulmonary vein and the interlobar branch of the pulmonary artery coursing posterior and medial to the veins. If the proximal arterial branch to the middle lobe could not be safely ligated from the fissure before, it should be easily accessible now. The fissure between the right middle and lower lobes can be completed using serial application of the GIA staplers by keeping the right middle lobe and the right middle-lobe bronchus to one side and the right lower lobe

Figure 2 Right upper lobectomy. Shown is the surgeon's view of the anterior right hilum. The apical venous branches of the superior pulmonary vein obscure the interlobar pulmonary artery and, to a lesser degree, the truncus anterior branch. Division of these venous branches during upper lobectomy improves exposure of the truncus anterior. The splitting of the main pulmonary artery into its two main branches may occur more proximally, and care should be taken to identify both branches before either one is divided. Another significant possible variation is a branch of the middle-lobe vein that arises from the intrapericardial portion of the superior pulmonary vein.

with the basilar branches of the pulmonary artery and the right lower-lobe bronchus to the other side.

Right middle-lobe bronchus The middle lobe is then rotated superiorly and posteriorly to expose the right middle-lobe bronchus [see Figure 3], which usually arises anterior and inferior to the right middle-lobe branches of the pulmonary artery. The basilar artery branches to the right lower lobe are gently mobilized posteriorly to expose the bronchus intermedius and the origin of the right middle-lobe bronchus. Peribronchial lymph nodes located in this region should be dissected and removed, with care taken not to injure the bronchial arterial branches. Once the bronchus is free, it is either divided and ligated with an automatic stapler or transected and oversewn as previously described (see above).

Right Lower Lobectomy

Pulmonary artery: superior segmental branch and basilar branches Once again, the pulmonary artery is exposed within the oblique fissure. The pulmonary branches to the superior segment and the basilar segments of the right lower lobe are identified [see Figure 1]. Most of the time, there is one branch to the superior segment of the right lower lobe; however, at times there are two branches, and, rarely, there is a common branch that gives rise to the posterior ascending branch of the right upper lobe and the superior segmental branch of the right lower lobe. Careful identification of the pulmonary artery is important. All branches within the fissure are identified, including the middle-lobe artery and the posterior ascending branch to the right upper lobe. The superior

segmental artery is encircled and doubly ligated, with care taken not to injure the posterior ascending branch if it arises from or close to the origin of the superior segmental branch. The basilar segmental branches are then encircled and doubly ligated, with the same care taken not to injure the middle-lobe branch. Both vessels are then divided.

Fissure between the right upper lobe and right lower lobe The fissure between the superior segment of the lower lobe and the posterior segment of the upper lobe is frequently incomplete. If necessary, it is completed as previously described [see Right Upper Lobectomy, above]. The pleura is incised along the bronchus intermedius, and the lymph node (sump node) just distal to the takeoff of the right upper-lobe bronchus is removed so that the previously dissected pulmonary artery is exposed. Serial application of GIA staplers is employed to complete the fissure.

Fissure between the right middle lobe and right lower lobe The fissure between the middle and lower lobes may also have to be completed (although, in many cases, it is congenitally complete). The pleura is incised within the anterior hilum to allow identification of the superior and inferior pulmonary veins. The basilar segmental bronchi and the middle-lobe bronchus should be exposed. Removal of lymphoid tissue allows easy application of a GIA stapler to complete the fissure.

Pulmonary vein: inferior pulmonary vein The inferior pulmonary vein is then encircled as it exits the pericardium [see Figure 4]. This step is facilitated by dissecting the superior edge of the inferior pulmonary vein with the lung rotated first anteriorly and then posteriorly. Once encircled, the pulmonary vein can easily be ligated and divided with a vascular stapler. An infrequent anatomic variant is a vein draining the posterior segment of the right upper lobe into the inferior pulmonary vein. Although an effort can be made to save this branch, there is adequate collateral venous drainage within the right upper lobe to allow this branch to be sacrificed without consequences.

Figure 3 Right middle lobectomy. Shown is the surgeon's view of the right middle-lobe bronchus. Gentle retraction of the basilar segmental artery to the lower lobe posteriorly allows clear visualization of the origin of the middle-lobe bronchus.

Figure 4 Right lower lobectomy. Shown is the surgeon's view of the right inferior pulmonary vein. For encirclement of this vein, dissection may also have to be performed on its anterior surface. The branch to the superior segment can be seen overlying the origin of the superior segmental bronchus.

Right lower-lobe bronchus Division of the lower-lobe bronchus is best accomplished through the fissure; this approach facilitates identification of the middle-lobe bronchus and helps prevent inadvertent damage to or compromise of the origin of this structure. Level 11 and 12 lymph nodes are cleared distally along the bronchi to expose the origin of the superior segmental bronchus [see Figure 5]. In some patients, there is adequate length to permit oblique placement of a stapler for control of all of the lower-lobe segmental bronchi without compromise of the middle-lobe bronchus. If this step is not possible, separate ligation and division of the superior segmental bronchus and of all the basilar bronchi as a unit should be performed.

The lung is rotated anteriorly, and the bronchus intermedius is dissected distally until the origin of the superior segmental bronchus is identified from this side. The branch of the inferior pulmonary vein draining the superior segment will be encountered and should be mobilized distally to allow adequate exposure of the superior segmental bronchus origin. This bronchus can now be encircled, ligated, and divided with a stapler or divided and oversewn.

Next, the basilar segmental bronchi are encircled at a point where closure will not affect airflow to the middle-lobe bronchus. Appropriate placement is confirmed by asking the anesthesiologist to ventilate the right lung while the stapler or clamp is applied to the base of the basilar bronchi. If placement is adequate, the basilar segmental bronchi are ligated and divided.

Right Pneumonectomy

Pulmonary artery: right main trunk With the pleura incised circumferentially around the hilum, the lung is rotated inferiorly and posteriorly [see Figure 2]. The main trunk of

the right pulmonary artery is exposed as it exits the pericardium posterior to the vena cava. Care is taken not to dissect distally on the vessel and not to encircle only the truncus anterior branch by mistake. Ligation and division of the right pulmonary artery can be accomplished in several different ways; either dividing the vessel between clamps and oversewing it with 3-0 nonabsorbable suture material or using vascular staplers is acceptable.

Pulmonary vein: superior and inferior pulmonary vein Next, attention is directed toward the superior pulmonary vein. The vessel is mobilized on its superior and inferior aspects with blunt and sharp dissection, encircled with blunt dissection, and ligated and divided with either clamps or a vascular stapler. With the lung retracted superiorly, the inferior pulmonary vein is dissected as in a right lower lobectomy [see Figure 4]. Once isolated, this vein is also ligated and divided as previously described (see above).

Right mainstem bronchus With the lung retracted anteriorly, attention is directed toward the right mainstem bronchus. The subcarinal lymph nodes are mobilized, and the bronchial artery on the posterior medial aspect of the right mainstem bronchus is controlled. The remaining peribronchial tissues are then mobilized distally with blunt and sharp dissection. To avoid leaving a long bronchial stump, exposure of the bronchus to within 1 cm of the carina is advisable.

The bronchus can be closed with a TA stapler loaded with 4.8 mm staples. The staples should be oriented so as to allow good approximation of the anterior and posterior membranous walls. If suture closure is selected instead, the bronchus is divided with the clamp placed on the distal bronchus to prevent spillage. The open end of the bronchus is then closed with nonabsorbable simple sutures, with the cartilaginous wall

Figure 5 Right lower lobectomy. Shown is the surgeon's view of the right fissure after division of the lower-lobe vessels. The decision whether to divide the bronchi separately or to transect them with a single oblique application of the stapler depends on the proximity of the middle-lobe bronchus to the superior segmental and basilar bronchi.

approximated to the membranous wall. To guard against necrosis of the bronchus, care should be taken not to tie the sutures too tightly. Coverage of the pneumonectomy stump with viable tissue is preferred, especially if the patient has received or will receive chemotherapy, radiation therapy, or both. The ideal choice for this purpose is either a rotated intercostal muscle flap or a pericardial fat pad rotational flap. The flap is secured with carefully placed 4-0 polypropylene sutures.

In the preceding description, the artery is divided first, followed by the individual veins and, finally, by the bronchus; however, the steps of this operation can be carried out in any order. The position of the tumor may make the approach we describe difficult. For example, an anteriorly placed tumor may hinder exposure of the anterior hilum. In this situation, the bronchus can be divided first, and the pulmonary artery can be approached from the posterior hilum. As another example, if the tumor is very proximal, the pericardium can be entered via a U-shaped incision along the anterior, caudal, and posterior hilum. The pulmonary veins can then be divided en masse as they originate from the left atrium, and the pulmonary artery can be divided as it courses posterior to the ascending aorta.

LEFT LUNG

Left Hilar Dissection

In the left chest cavity, it is important to identify the inferior pulmonary vein, pulmonary artery, bronchus, and superior pulmonary artery. Retract the lung anteriorly and take down the mediastinal pleura to expose the inferior pulmonary vein and continue superiorly to expose the left main bronchus and the pulmonary artery. With the lung retracted inferiorly, dissection continues proximally along the pulmonary artery. The pleura is incised under the arch of the aorta to expose the left main pulmonary artery. A variable number of small vessels and vagal branches to the lung are encountered that must be ligated and divided. Care is taken not to injure the recurrent laryngeal nerve as it branches from the vagus and travels under the arch just distal to the ligamentum arteriosum. With the lung now retracted posteriorly, the mediastinal pleura is opened parallel to and posterior to the course of the phrenic nerve [see Figure 6]. This will expose the main trunk of the left pulmonary artery and the superior pulmonary vein.

Left Upper Lobectomy

Pulmonary artery: apicoanterior, posterior, and lingular The interlobar fissure is developed with a combination of sharp and electrocautery dissection. The posterior aspect of the fissure, between the apicoposterior segment of the left upper lobe and the superior segment of the left lower lobe, is completed (with a linear stapler if necessary) to expose the proximal portion of the pulmonary artery. The left upper lobe is then retracted anteriorly and superiorly to expose the pulmonary arteries supplying the lobe [see Figure 7]. The left upper-lobe pulmonary artery anatomy is most variable among the lobes. The most common anatomy is three branches from the pulmonary artery: apicoanterior, posterior, and lingular branches. However, not infrequently, multiple posterior apical branches are encountered; in fact, as many as seven vessels supplying the left upper lobe may be identified. Typically, the posterior segmental branch frequently arises directly opposite the superior segmental branch to the lower lobe, as well as a

more distally situated lingular branch. These vessels should be identified, individually ligated, and divided.

Next, the whole lung is retracted inferiorly to expose the aortic arch. A large arterial branch supplying the apicoposterior aspect of the upper lobe is usually encountered. Although the superior and posterior aspects of this artery are easily dissected, the anterior aspect is frequently obscured by an apical branch of the superior pulmonary vein; division of this venous branch may improve exposure and facilitate control of the artery. Once the artery is encircled, it is ligated and divided. To prevent avulsion of this vessel from the main pulmonary artery, care must be taken not to exert excessive traction on the lung.

Pulmonary vein: superior pulmonary vein The superior pulmonary vein can then be identified easily. If the apical branch was not previously ligated, the surgeon should make every effort not to damage the pulmonary artery branches that lie posterior to this portion of the vein. The majority of the superior pulmonary vein lies anterior to the left upper-lobe bronchus. Once this vein is encircled, it is ligated and divided.

Left upper-lobe bronchus Attention is then redirected toward the fissure, and the peribronchial nodal tissue surrounding the left upper-lobe bronchus is swept distally with blunt and sharp dissection. The fissure between the lingula and the lower lobe is completed with serial application of GIA staplers [see Figure 8]. The left upper-lobe bronchus is encircled and either clamped or controlled with a TA stapler. To prevent inadver-

Figure 6 Left upper lobectomy. Shown is the surgeon's view of the anterior left hilum. The apical branches of the superior pulmonary vein course anterior to the apicoposterior branches of the pulmonary artery. If additional vessel length is needed because of the presence of a central tumor, the pericardium may be entered and the vein divided at that location.

Figure 7 Left upper lobectomy. Shown is the surgeon's view of the left interlobar fissure. The recurrent laryngeal nerve can be seen coursing lateral to the ligamentum arteriosum. The arterial branches supplying the left upper lobe between the apicoposterior segmental branch and the lingular branch can vary substantially in number and size. Another frequently encountered variation is a distal lingular branch that arises from a basilar segmental branch.

Figure 8 Left upper lobectomy. Shown is the surgeon's view of the left fissure after division of the upper-lobe arteries. Care should be taken not to injure the pulmonary artery inadvertently when applying a stapler.

tent injury, the pulmonary artery branches to the lower lobe should be gently retracted posteriorly during stapler placement. With the stapler applied (or the clamp in place), the anesthesiologist ventilates the left lung to verify that air is flowing freely to the entire left lower lobe. Once unobstructed airflow is confirmed, the stapler is fired and the bronchus is divided.

Left Lower Lobectomy

Pulmonary artery: superior segmental and basilar

As in a left upper lobectomy, dissection begins within the interlobar fissure. The pulmonary artery is identified, and the branches to the upper and lower lobes are dissected [see Figure 7]. The superior segmental artery is encircled first and is ligated and divided; not uncommonly, there are actually two separate superior segmental arteries. The basilar segmental arteries are then encircled distal to the origin of the lingular artery. These vessels are also ligated and divided, with care taken not to encroach on the blood flow to the lingula.

Pulmonary vein: inferior pulmonary vein The lung is rotated superiorly to expose the inferior pulmonary vein. As in a right lower lobectomy, the vein is encircled by dissecting first on its anterior surface with the lung rotated posteriorly, then on its posterior surface with the lung rotated anteriorly [see Figure 9]. Once the vein is encircled, it is ligated and divided.

Left lower-lobe bronchus Attention is then redirected toward the interlobar fissure, and the left lower-lobe bronchus

Figure 9 Left lower lobectomy. Shown is the surgeon's view of the left inferior pulmonary vein. The left side, unlike the right side, affords only limited access to the subcarinal space. However, the length of the inferior pulmonary vein outside the pericardium is greater on the left side than on the right.

is identified [see Figure 10]. The origin of the bronchus is cleared by sweeping nodal tissue distally with blunt and sharp dissection. The upper-lobe branches of the pulmonary artery are gently retracted superiorly to allow placement of a TA stapler on the bronchus. With the stapler applied, the anesthesiologist ventilates the left lung to confirm the adequacy of airflow to the upper lobe. The stapler is fired, and the bronchus is divided distal to the staple line.

Left Pneumonectomy

Pulmonary artery: left main pulmonary artery The initial steps of a left pneumonectomy are similar to those of a left upper lobectomy. The lung is retracted caudally, and the pleura is incised along the course of the aortic arch [see Figure 7]. The superior and posterior surfaces of the pulmonary artery are dissected as it enters the thorax under the aortic arch. Once the perivascular space is entered, the entire vessel can usually be encircled with blunt dissection. If the superior pulmonary vein's apical branch limits access to the anterior surface of the pulmonary artery, the branch may be ligated and divided first to improve exposure of the artery; alternatively, the superior pulmonary vein itself may be ligated and divided first to facilitate arterial exposure (see below).

Once the pulmonary artery is encircled, the vessel can be ligated and divided. Our preferred method is to use an endovascular GIA stapler, the advantages of which include its rapidity of use, its consistently reproducible results, and its ability to control the vessel along a broad surface. Mass ligation is not advisable, because the risk of dislocation of the tie is too great. When the length of exposed artery is too short or a stapler cannot be placed safely, the surgeon may apply vascular clamps to the proximal and distal portions of the vessel instead. Once the vessel is divided, the proximal end may be oversewn with a continuous polypropylene suture.

If additional vessel length is required because of the presence of a proximal tumor, the ligamentum arteriosum may be divided. The recurrent laryngeal nerve should be identified and preserved. In dividing the left pulmonary artery proximal

Figure 10 Left lower lobectomy. Shown is the surgeon's view of the left fissure after division of the lower-lobe vessels. In this procedure, a single oblique transection of the entire left lower-lobe bronchus can be employed without any concern that a proximal bronchus will be compromised; this step would not be feasible in a right lower lobectomy, in that the right middle-lobe bronchus arises from the bronchus intermedius.

to the ligamentum arteriosum, care should be taken not to narrow the main pulmonary artery and thereby reduce right-side blood flow. For maximal safety, systemic blood pressures and oxygenation should be evaluated for 15 to 20 seconds after application of the clamp or stapler but before ligation.

Pulmonary vein: superior and inferior pulmonary vein With the lung retracted posteriorly, the pleura is incised posterior to the course of the phrenic nerve, and the superior pulmonary vein is identified [see Figure 6]. The vein is encircled with blunt dissection, then ligated and divided. As noted (see above), the apical branch usually travels across the apical branch of the pulmonary artery, and care should be taken not to injure this vessel during dissection.

The lung is then retracted superiorly to expose the inferior pulmonary vein. Dissection is performed on the anterior and posterior aspects of the inferior pulmonary vein, and blunt dissection is used to achieve complete encirclement of the vein [see Figure 9], which is ligated and divided.

Left main bronchus Next, the lung is retracted anteriorly and superiorly. Complete dissection of the subcarinal lymph nodes is performed, facilitated by division of one or two pulmonary branches of the left vagus nerve and both bronchial arteries. Gentle traction is applied in conjunction with blunt dissection to allow encirclement of the proximal left mainstem bronchus [see Figure 11]. An effort should be made to encircle the bronchus within 1 cm of the carina. A TA stapler is then passed around the left mainstem bronchus and applied at this point. If excessive traction is required to achieve this placement, the bronchial stump can be left slightly longer: 1 to 1.5 cm, as measured from the carina. The stapler is fired, and the bronchus is divided distal to the staple line.

Frequently, the position of the bronchial stump under the aortic arch and deep within the mediastinum renders coverage of the stump unnecessary. If the surgeon is concerned about

Figure 11 Left pneumonectomy. Shown is the surgeon's view of the posterior left hilum. The carina is located deep under the aortic arch. A left-side double-lumen tube or bronchial blocker may have to be withdrawn to afford better exposure of the proximal left mainstem bronchus. The orientation of the superior pulmonary vein and the pulmonary artery (anterior and superior to the bronchus, respectively) should be noted.

possible stump dehiscence (e.g., in a patient who has undergone high-dose preoperative radiotherapy), coverage with a flap from the pericardial fat pad or intercostal muscle is appropriate.

Postoperative Management

A key to successful postoperative management after pulmonary resection is pain control, pulmonary toilet and chest tube management. Thoracic epidural can provide great pain relief after the operation. If this modality is not available or not efficacious, patient controlled analgesia with or without continuous local anesthetic to the thoracotomy incision can be a good alternative. Although adequate pain control is one of the key elements of good pulmonary toilet it is not sufficient by itself. Patient education should begin preoperatively with clear explanation of the goals of pulmonary toilet and the methods used to achieve this. This includes coughing, deep breathing, usually assisted with an incentive spirometer, ambulation, bronchodilators, and, if necessary, nasotracheal suctioning or even flexible bronchoscopy. An x-ray is obtained after the operation to evaluate for appropriate lung expansion, shift of the mediastinum and the diaphragm. After a lobectomy or any lesser resection, the chest tube is usually placed on suction at -20 cm H_2O then transitioned to a water seal once there is a minimal air leak. Although there are wide variations in chest tube management most surgeons will

remove the tube when the air leak has resolved and the output is less than 300–400 cc in 24 hours. Patients are then transitioned to oral pain medication and discharged home.

15 DIAPHRAGMATIC PROCEDURES

Ayesha S. Bryant, MSPH, MD, and Robert James Cerfolio, MD, FACS, FCCP

Although the diaphragm is sometimes thought of as little more than a partition between the thoracic organs and the abdominal organs, it is, in fact, a dynamic anatomic structure that plays a pivotal role in the physiology of respiratory mechanics. For example, paralysis of just one hemidiaphragm can lead to the loss of 50% of a patient's vital capacity.¹ Like any other anatomic structure, the diaphragm may be affected by either benign or malignant conditions. Overall, benign diseases of the diaphragm (e.g., paralysis) are far more common than malignant ones. With either type of condition, however, the development of a safe surgical treatment strategy depends on a solid knowledge of diaphragmatic anatomy and physiology. Accordingly, we begin with a brief review of the embryology and anatomy of the diaphragm. We then describe the main procedures performed to treat the more common congenital diseases (e.g., congenital diaphragmatic hernia [CDH]) and acquired pathologic conditions (e.g., paralysis and tumor) that affect this structure.

Anatomic Considerations

DEVELOPMENTAL ANATOMY

The diaphragm is a modified half-dome of musculo-fibrous tissue that lies between the chest and the abdomen and serves to separate these two compartments. It is formed from four embryologic components: (1) the septum transversum, (2) two pleuroperitoneal folds, (3) cervical myotomes, and (4) the dorsal mesentery. Development of the diaphragm begins during week 3 of gestation and is complete by week 8. Failure of the pleuroperitoneal folds to develop, with subsequent muscle migration, results in congenital defects.

CLASSICAL ANATOMY

The diaphragmatic musculature originates from the lower six ribs on each side, from the posterior xiphoid process, and from the external and internal arcuate ligaments. A number of different structures traverse the diaphragm, including three distinct apertures (foramina) that allow the passage of the vena cava, the esophagus, and the aorta [see Figure 1]. The aortic aperture is the lowest and most posterior of the diaphragmatic foramina, lying at the level of the 12th thoracic vertebra. Besides the aorta, the thoracic duct and, sometimes, the azygos and hemiazygos veins also pass through this aperture. The esophageal aperture is the middle foramen; it is surrounded by diaphragmatic muscle and lies at the level of the 10th thoracic vertebra. The vena caval aperture is the highest of the three foramina, lying level with the disk space between T8 and T9.

VASCULAR SUPPLY

The diaphragm is supplied by the right and left phrenic arteries, the intercostal arteries, and the musculophrenic

branches of the internal thoracic arteries. Some blood is supplied by small branches of the pericardiophrenic arteries that run with the phrenic nerve, mainly where the nerves penetrate the diaphragm. Venous drainage occurs via the inferior vena cava and the azygos vein on the right and via the suprarenal and renal veins and the hemiazygos vein on the left.

INNERVATION

The diaphragm receives its muscular neurologic impulse from the phrenic nerve, which arises primarily from the fourth cervical ramus but also has contributions from the third and fifth rami. The phrenic nerve originates around the level of the scalenus anterior and runs inferiorly through the neck and thorax before reaching its terminal point, the diaphragm. Because the phrenic nerve follows such a long course before reaching its final destination, a number of processes can disrupt the transmission of neurologic impulses through the nerve at various points and thereby cause diaphragmatic paralysis.

Figure 1 Shown is an inferior view of the diaphragm.

Procedures for CDH

REPAIR OF BOCHDALEK HERNIA

Bochdalek hernia, named after the Czech anatomist Vincent Alexander Bochdalek, is the most common form of CDH and is also the most common surgical emergency in neonates.¹ It involves an opening on the left side of the diaphragm. The stomach and intestines usually herniate into the thoracic cavity. The usual presenting symptoms are severe respiratory distress and a scaphoid abdomen. The primary pathologic condition is the presence of posterolateral defects of the diaphragm, which result either in maldevelopment of the pleuroperitoneal folds or in improper or absent migration of the diaphragmatic musculature.

Bochdalek hernias occur in approximately one of every 2,500 live births and are twice as common in male neonates as in female neonates. Mortality ranges from 45 to 50%. The bulk of the morbidity and mortality of CDH is attributable to the resultant hypoplasia of the lung on the affected side and to various associated abnormalities (e.g., malrotation of the gut, neural tube defects, and cardiovascular anomalies).

Preoperative Evaluation

Prenatal ultrasound examination accurately diagnoses CDH in 40 to 90% of cases.² In most instances, the examination is performed to rule out polyhydramnios. It is noteworthy that polyhydramnios is present in as many as 80% of pregnant women whose fetuses have CDH.³ In neonates with CDH, besides the upper gastrointestinal tract, parts of the colon, the spleen, the kidneys, and the pancreas may herniate, and the abnormal position of these organs can be identified by means of ultrasonography. Malrotation and malfixation of the small bowel should be ruled out. Once the diagnosis is confirmed, additional radiographic, echocardiographic, and ultrasonographic studies should be performed to rule out associated anomalies.

Operative Technique

As a rule, neonates with Bochdalek hernias are taken to the operating room immediately after birth. Some studies, however, have shown that delayed surgical repair yields improved survival rates.⁴

For left-side hernias, a transabdominal subcostal approach is generally preferred, whereas for right-side hernias, a thoracic approach may be more useful. The herniated organs are returned to the peritoneal cavity. The lung is inspected, but no attempt to expand the hypoplastic lung should be made. If any extralobar pulmonary sequestration is present (as is occasionally the case), it should be excised. Most of the defects may be closed primarily with interrupted nonabsorbable sutures; particularly large defects may be closed with a prosthetic patch. The left pleural space is drained with a chest tube, which should be placed on water seal.

Some surgeons have attempted surgical correction of severe Bochdalek hernias in the prenatal period. The safety and feasibility of this therapeutic approach continue to be debated. Prenatal correction of these hernias poses a risk to both the mother and the fetus, with possibly fatal results for both.⁵

REPAIR OF MORGAGNI HERNIA

Morgagni hernias, named after the Italian anatomist and pathologist Giovanni Battista Morgagni, are related to maldevelopment of the embryologic septum transversum and to failed fusion of the sternal and costal fibrotendinous elements of the diaphragm.⁶ The Morgagni hernia involves an opening on the right side of the diaphragm. The liver and intestines usually herniate into the thoracic cavity. These hernias are generally asymptomatic⁷ and are usually detected as incidental findings on radiographs. Accordingly, the average age at diagnosis is typically greater for Morgagni hernia than for Bochdalek hernia: in one report, the mean age at which the former was diagnosed was 45 years.⁸ Morgagni hernias are most commonly seen on the right side. The hernia sac usually contains omentum, but it may also contain part of the transverse colon or, less commonly, parts of the stomach, the liver, or the small bowel; almost any upper abdominal structure may herniate in this setting.

Preoperative Evaluation

On chest radiography, a Morgagni hernia appears as a mass at the right cardiophrenic angle [see Figure 2]. Computed tomography (CT) of the chest and abdomen, liver scintigraphy, and multiplanar magnetic resonance imaging (MRI) are occasionally helpful in the diagnostic process.

Operative Technique

Morgagni hernias can be repaired via a subcostal, a paramedian, or a midline incision. We prefer to use an upper midline abdominal incision. Once the peritoneal cavity is entered, the hernia sac is identified just posterior to the xiphoid and the posterior sternal border and then opened. The herniated abdominal viscera are restored to their normal abdominal anatomic positions, and the sac is ligated. The entire hernia sac is defined, resected, and closed. The diaphragmatic defect may be repaired in several different ways, depending on its size and position. Because there is weak tissue in the area of the defect, we generally use a prosthetic patch for the repair. Either polypropylene mesh (e.g., Marlex; C. R. Bard, Inc., Murray Hill, New Jersey) or polytetrafluoroethylene (PTFE) mesh (e.g., Gore-Tex; W. L. Gore and Associates, Newark, Delaware) may be used for this purpose. We prefer PTFE because it may cause fewer adhesions to the underlying abdominal structure, which may be an important consideration if further abdominal surgery subsequently proves necessary. The prosthetic patch is sewn to the midline abdominal fascia, with wide bites taken to prevent an abdominal incisional hernia. The rest of the patch is sewn to the thickened investing fascia that made up the edges of the hernia sac. As noted, the frequently marginal quality of this tissue is the reason why a patch repair is almost always required.

Repair of a Morgagni hernia via a thoracic incision follows the same basic principles. The hernia sac is entered, the visceral contents are mobilized and reduced into the abdomen, the sac is resected, and the diaphragm is repaired. Again, the closure should be completed without tension. If the defect cannot be closed with horizontal mattress sutures, a prosthetic patch should be used.

Figure 2 Repair of Morgagni hernia. The differential diagnosis of a cardiophrenic-angle mass includes pericardial fat, a lipoma, a pericardial cyst, a Morgagni hernia, and a thymoma. Shown are (a) chest x-rays and (b) chest computed tomographic scans from a 33-year-old man with an incidental finding of a Morgagni hernia.

Complications

The potential complications of surgical treatment of Morgagni hernia depend to an extent on the type of procedure undertaken to repair the defect. Laparoscopy may result in failure to reduce the contents of the hernia sac, which

necessitates conversion to an open procedure. Laparotomy has been associated with postoperative pleural effusion,⁹ wound infection,¹⁰ deep vein thrombosis,¹¹ and pulmonary embolism.¹² Thoracotomy has been associated with pneumonia, sepsis, and bowel obstruction in the postoperative period.¹³

Outcome Evaluation

Most patients do not have any significant postoperative limitations after repair of a Morgagni hernia, nor are such hernias likely to recur. In one study, 16 patients who underwent transthoracic repair of a Morgagni hernia were followed for 5.7 years; no recurrences or symptoms related to the operation were reported.¹⁴

Procedures for Diaphragmatic Paralysis

The diaphragm is the most important of the respiratory muscles: diaphragmatic contraction decreases intrapleural pressure during inspiration, expands the rib cage, and thereby facilitates the movement of gases into the lungs. Accordingly, paralysis of the diaphragm can have a major adverse effect on respiratory function. Diaphragmatic paralysis may involve either the whole diaphragm (bilateral paralysis) or only one leaflet or hemidiaphragm (unilateral paralysis). The possible causes of diaphragmatic paralysis are numerous [see Table 1]; the most common causes are phrenic nerve trauma related to a surgical procedure (e.g., stretching, crushing, or transection) and invasion by a malignant neoplasm.

DIAPHRAGMATIC PPLICATION FOR UNILATERAL PARALYSIS

Preoperative Evaluation

With unilateral diaphragmatic paralysis, the paralyzed hemidiaphragm paradoxically moves upward on inspiration and downward on expiration, passively following changes in intrapleural and intra-abdominal pressure. Patients with a paralyzed hemidiaphragm who are otherwise healthy usually have no symptoms at rest but experience dyspnea during exertion and show a decrease in exercise performance.

Table 1 Common Causes of Diaphragmatic Paralysis

Neurologic conditions
Spinal cord transection
Multiple sclerosis
Amyotrophic lateral sclerosis
Cervical spondylosis
Poliomyelitis
Guillain-Barré syndrome
Phrenic nerve dysfunction
Compression by tumor
Cardiac surgery cold injury
Blunt trauma
Idiopathic phrenic neuropathy
Diabetes mellitus
Postviral phrenic neuropathy (herpes zoster)
Radiation therapy
Cervical chiropractic manipulation
Myopathic conditions
Limb-girdle dystrophy
Hyperthyroidism/hypothyroidism
Malnutrition
Acid maltase deficiency
Connective tissue disease
Systemic lupus erythematosus
Dermatomyositis
Mixed connective tissue disease
Amyloidosis
Idiopathic myopathy
Muscular dystrophy
Multiple sclerosis

Physical examination may reveal dullness to percussion and an absence of breath sounds over the lower chest on the involved side.

In most cases, the diagnosis of hemidiaphragmatic paralysis is suspected on the basis of incidental findings on a chest x-ray. Typically, the roentgenogram reveals an elevated hemidiaphragm, diminished lung volume, and basilar atelectasis. Fluoroscopy may also be performed. The diagnosis is confirmed by performing a fluoroscopic sniff test, in which paradoxical elevation of the paralyzed diaphragm is observed with sniffing.¹⁵ The sniff test is the gold standard for the diagnosis of this condition. In certain patients, a chest CT scan may be indicated for evaluating the potential cause of the paralysis. If an obvious cause is not apparent from the history or a previous evaluation, CT scanning of the chest should be performed to ensure that no pathologic process is compressing or invading the phrenic nerve. Similarly, MRI of the neck or the spine may be indicated in certain patients to look for conditions that might be causing the diaphragmatic paralysis.

Two other tests that are also (albeit less commonly) used for the diagnosis of unilateral diaphragmatic paralysis are electromyography and transdiaphragmatic pressure assessment. In the first, the phrenic nerve is electrically stimulated in the neck in an effort to distinguish between neuropathic and myopathic causes of paralysis. In the second, transdiaphragmatic pressures are measured by placing a thin-walled balloon transnasally at the lower end of the esophagus in such a way as to reflect changes in pleural pressure; a second balloon manometer is then placed in the stomach in such a way as to reflect changes in intra-abdominal pressure. The difference between the two pressures is the transdiaphragmatic pressure. Measurement of transdiaphragmatic pressure can help differentiate diaphragmatic paralysis from other causes of respiratory failure.

Yet another test involves measurement of maximal inspiratory pressures. Patients with diaphragmatic dysfunction and paralysis show a decrease in their maximal inspiratory pressures. These patients cannot generate high negative inspiratory pressures; thus, their maximal inspiratory pressures will be less negative than -60 cm H₂O.

Operative Planning

Surgical treatment of hemidiaphragmatic paralysis is reserved for symptomatic patients who, after a follow-up period of at least 6 months, have persistent shortness of breath with exertion that is sufficiently pronounced to interfere with lifestyle. For a patient to be considered for operation, the sniff test should show significant paradoxical motion.

The basic principle of the surgical procedure is to “reef” (i.e., reduce the surface area of) the redundant floppy diaphragm by plicating it. This measure lowers the resting position of the hemidiaphragm and thus affords the lung the opportunity to expand fully. The effective result is an increase in the functional vital capacity of the ipsilateral lung. The results of plication have been shown to be better in children compared to adults. Plication is of limited benefit in weaning ventilated adults; however, it still results in lifetime improvement in nonventilated adults.¹⁶ A couple of studies have found

that plication of the diaphragm led to long-term improvements in pulmonary function test results, as well as reduced dyspnea.^{17,18}

Operative Technique

Diaphragmatic plication may be performed with either sutures or staples; we prefer sutures for this procedure. The chest is entered through a thoracotomy in the seventh or eighth intercostal space. Horizontal mattress sutures buttressed with Teflon pledgets are then placed in a lateral-to-medial direction [see Figure 3]. We typically use monofilament nonabsorbable sutures that pass easily through the muscle and can be tightened without dragging through tissue. To distribute the tension, multiple sutures must be placed; this is especially important on the right side, where the diaphragm must be pulled down against the upward force exerted by the presence of the right hemiliver. When the sutures are tied, the hemidiaphragm should be almost back to its normal anatomic location. Care must be taken to ensure that the repair is not under undue tension: excessive tension is likely to result in early dehiscence. Occasionally, a prosthetic patch may be used to buttress the repair further, but in the majority of cases, this measure should be unnecessary. If the choice is made to use staples rather than sutures, care must be taken to ensure that the underlying abdominal contents are not caught in the staple line.

Diaphragmatic plication can also be performed via video-assisted thoracoscopic approach. Some studies have shown that the minimally invasive approach reduces the risk and the recovery time when compared to a thoracotomy.¹⁹

Figure 3 Diaphragmatic plication. Shown is suture plication of the right hemidiaphragm. Placement of sutures buttressed with pledgets extends anteriorly to the level of the vena cava.

DIAPHRAGMATIC PACING FOR BILATERAL PARALYSIS

Preoperative Evaluation

In patients with bilateral diaphragmatic paralysis, the respiratory accessory muscles assume all the work of breathing by contracting more intensely. Both hemidiaphragms move upward on inspiration, concomitant with inward (rather than the normal outward) movement of the abdominal wall.²⁰ Patients typically present with severe respiratory failure or with dyspnea (sometimes misinterpreted as a sign of heart failure) that worsens in the supine position, and they generally exhibit tachypnea and rapid, shallow breathing when in the recumbent position. Increased expenditure of effort in the struggle to breathe may fatigue the accessory muscles and lead to ventilatory failure. Patients also report anxiety, insomnia, morning headache, excessive daytime somnolence, confusion, fatigue, poor sleep habits, and signs of cor pulmonale.²¹

During physical examination, auscultation of the chest reveals limitation of diaphragmatic excursion and bilateral lower-chest dullness with absent breath sounds. The finding that establishes the diagnosis is a paradoxical inward movement of the abdomen with inspiration. As with unilateral diaphragmatic paralysis, however, it is more common for the diagnosis to be suspected on the basis of a chest roentgenogram that shows bilateral diaphragmatic elevation and then confirmed by means of the sniff test.

Operative Planning

Treatment depends on the cause and severity of the diaphragmatic paralysis. Most patients are treated with ventilatory support, but some are treated with bilateral plication or with pacing (as shown in Figure 4). Plication for bilateral paralysis is performed in the same way as plication for unilateral paralysis [see Diaphragmatic Plication for Unilateral Paralysis, above], except that both hemidiaphragms are lowered.

There are patients who have suffered high cervical injuries and are either quadriplegic or have loss of the C3, C4, and C5 anterior horn cells in the nerve roots. These patients are on ventilators for life and usually nonambulatory. To date, two pacing devices have been approved by the Food and Drug Administration: the Mark IV Breathing Pacemaker System (Avery Biomedical Devices, Commack, New York) uses an electrode that is placed on the skeletonized phrenic nerve, and the NeuRx (Synapse Biomedical, Cleveland, Ohio) uses electrodes placed directly in the diaphragm fibers either video-assisted thoracoscopically or laparoscopically. Both are connected to a small receiving electrode unit placed under the skin. A battery-powered external transmitting box connected to an antenna is taped over the surface of the skin, just above the subcutaneous receiver. This transmitting box permits adjustment of pulse duration, pulse train duration, respiratory rate, pulse frequency, and current amplitude. In most patients, the only parameters that the clinician adjusts are current amplitude and respiratory rate.

Implantation of a diaphragmatic pacer requires experience on the part of the surgeon—not so much because of any particular technical demands imposed by the implantation itself but because of the procedures for diaphragm training that must be carried out in the postoperative period.

Figure 4 Diaphragmatic pacing. Shown are internal and external pacer connections.

Surgical implantation of a diaphragmatic pacer can be done via either a cervical approach or a thoracic approach. The primary advantage of the cervical approach is that it avoids the morbidity associated with bilateral thoracotomies, which may not be well tolerated in patients who have marginal pulmonary function or a history of severe pulmonary contusions. However, there are other ways of avoiding this morbidity, either laparoscopically, by video-assisted thoracoscopic surgery (VATS), or with a small muscle-sparing, rib-sparing, nerve-sparing thoracotomy.²² One disadvantage of the cervical approach is that in a small percentage of patients, the current amplitude necessary to stimulate the phrenic nerve results in transmission of the current through the soft tissues. The transmitted current stimulates the functioning portions of the brachial plexus, causing rhythmic jerking motions of the upper extremities. Another disadvantage is that a number of accessory nerve branches arise distal to the neck.

One advantage of the thoracic approach is that inadvertent stimulation of portions of the brachial plexus (as sometimes occurs with the cervical approach) may be avoided. Another advantage is that there is some neuroanatomic evidence that a small branch of the phrenic nerve joins the main nerve trunk only after it enters the chest cavity; thus, the thoracic approach may stimulate a larger portion of the phrenic nerve

than the cervical approach would. The disadvantage of the thoracic approach is the preconceived notion that entry into the chest is associated with a higher morbidity than entry into the neck.

Operative Technique

Cervical placement In the neck, the phrenic nerve runs between the scalenus anterior and the scalenus medius. A transverse skin incision is made in the midportion of the neck, just lateral to the sternocleidomastoid muscle, and the borders of the two scalene muscles are dissected. The scalene muscles are then divided, and the phrenic nerve is identified lying in a layer of fascia just anterior to the anterior surface of the scalenus medius. Identification of this nerve is often facilitated by the use of a handheld nerve stimulator. Intraoperative fluoroscopy allows observation of diaphragmatic contraction in response to phrenic nerve stimulation, which confirms that pacing is successful.

Once the phrenic nerve is identified, it is carefully dissected free of its investing fascia, and the Y-shaped electrode is placed under it and secured with sutures. Care must be taken to ensure that the nerve is not injured during this step. The connecting wire from the electrode is then tunneled subcutaneously to a subcutaneous pocket that is created just below the ipsilateral clavicle. The connections are made and sealed, and the small incisions are closed.

Thoracic placement In the thoracic approach, the chest is entered through a high thoracotomy (usually over the fourth interspace), and the proximal phrenic nerve is identified. On the right side, the nerve lies along the mediastinum, situated just anterior to the vena cava and coursing along the pericardial surface. On the left side, it lies on the pericardium for most of its length. The proximal nerve is freed of its fibrous investments, and the electrode is placed under it and secured with sutures. The electrode is connected to the receiver, which is placed in a subcutaneous pocket.

As noted (see above), there are alternative approaches to pacer implantation that avoid the cervical approach but also do not involve standard thoracotomies. For example, there is limited (but growing) experience with thoracoscopic placement of phrenic nerve pacing leads.²³ In addition, laparoscopic implantation of intramuscular pacing electrodes onto the inferior aspect of the diaphragm has been reported.²⁴

Taking into account all the advantages and disadvantages of each approach to pacer implantation, we generally prefer the thoracic approach, either via VATS or via a thoracotomy.^{23,25} The evolution of less invasive surgical techniques may allow the thoracic approach to be employed in patients who are unable to tolerate thoracotomy.

Complications

Besides the usual complications associated with any thoracic procedure (i.e., infection, bleeding, atrial fibrillation, and pneumonia), several specific complications are associated with diaphragmatic pacing. The most common of these are dislodgment of the pacer electrode, transmission of pacer impulses to the brachial plexus with resultant rhythmic jerking of the upper extremity (seen with cervical placement of the electrode), and hardware malfunction.

Outcome Evaluation

Retrospective analysis of the collective experience at a single center between 1981 and 1987 suggested that long-term pacing did not lead to progressive diaphragmatic dysfunction.²⁶ Six of the 12 patients in this cohort continued to undergo diaphragmatic pacing on a full-time basis for a median period of more than 14 years. Pacing was well tolerated in this group; the reasons for discontinuance included intercurrent medical illness and lack of social support. Concerns have been raised that prolonged diaphragmatic pacing might damage the phrenic nerve. In the series cited, however, the ability to pace the phrenic nerve was not lost in any of the patients, and the mean threshold currents for pacing did not change significantly over time.

Resection of Diaphragmatic Tumors

Primary tumors of the diaphragm are extremely rare. Benign tumors (e.g., lipomas and cystic masses) are more common than malignant tumors, which mostly are sarcomas of fibrous or muscular origin. Thoracic and abdominal tumors (e.g., bronchogenic carcinomas, pleural malignancies, and chest wall malignancies) may involve the diaphragm secondarily through direct extension. Malignant pleural mesothelioma represents a different scenario and is not discussed here. Schwannomas, chondromas, pheochromocytomas, and endometriomas have all been reported. Bilateral occurrence,

calcification, sharp margins, and flattened contours are indicative of a malignant process, such as pleural metastases, mesothelioma, or a primary diaphragmatic tumor.

The most common indication for diaphragmatic resection is mesothelioma. This remains true even though mesothelioma is relatively uncommon in comparison with bronchogenic malignancy and even though few patients with mesothelioma are actually candidates for resection. Again, resection of a mesothelioma is not addressed here. The ensuing operative description focuses on diaphragmatic resection to treat either a lung cancer invading the diaphragm or a primary diaphragmatic tumor [see Figure 5].

OPERATIVE TECHNIQUE

Once the decision is made to resect a tumor involving the diaphragm, the key considerations are (1) the surgical approach to be taken and (2) the placement of the incision in the diaphragm. We prefer a skin incision that is lower and slightly more anterior than a normal posterolateral thoracotomy; such an incision allows easy entry over the top of the seventh rib. After entry into the chest, the lung, the pericardium, and the pleural surface are carefully visualized and palpated to search for any signs of metastatic disease.

Next, the incision in the diaphragm is planned. Ideally, the incision should be made anterior or lateral to the tumor so that a hand can be placed easily into the peritoneal cavity [see Figure 5a]. Intra-abdominal palpation confirms that the tumor

Figure 5 Resection of diaphragmatic tumor. The patient has a right lower-lobe bronchogenic malignancy with erosion into the right hemidiaphragm. (a) The tumor is resected en bloc with the diaphragmatic fibers; the electrocautery is used to achieve clear surgical margins and hemostasis. (b) The defect in the right hemidiaphragm is closed with a mesh patch.

has not extended into underlying structures. This information is almost always gleaned from the preoperative CT scan, but if any uncertainty remains after the scan, diagnostic laparoscopy may be performed before the thoracotomy to look for possible tumor extension.

The tumor is then resected with 2 to 4 cm margins. The large arteries that course through the diaphragmatic fibers are ligated. It is our practice also to place a few silk sutures (stay stitches) in the edges of the defect; this prevents the edges from retracting, helps keep the defect as small as possible, and keeps abdominal contents from interfering with the resection. In addition, we place clips on the edges for guidance purposes in case adjuvant radiotherapy is delivered after the operation. If adequate margins are obtained, which is usually relatively easy in a diaphragmatic resection, postoperative radiotherapy should be unnecessary. If, however, the tumor abuts vital structures (e.g., the suprahepatic vena cava), postoperative radiotherapy may have a useful role to play.

Once the entire tumor has been resected and clear margins have been confirmed by frozen-section examination, the diaphragm is reconstructed. Primary repair is rarely indicated because in most cases, the defect is too large and the tension on the repair would be too great. Moreover, the tissue in the anterior aspect of the diaphragm is thin and is likely to tear

under tension. Accordingly, repair with a prosthetic patch is the usual choice. Infection of such a patch is exceedingly rare, and with the exception of the cost, there is little downside to the use of prosthetic material in this setting. As in the repair of a CDH, we prefer PTFE mesh [see Figure 5b] to polypropylene mesh because it is less likely to adhere to underlying abdominal structures.

The mesh patch is sewn to the edges of the defect (preferably with nonabsorbable suture material, such as 0 polypropylene), starting at the most anterior and inferior portions of the opening and continuing toward the surgeon [see Figure 5]. The inferior half of the repair is done with a continuous suture. The repair is completed with two or three sutures, which are tied circumferentially. To prevent paradoxical motion, the diaphragm must not be too redundant or floppy. It should remain in the normal anatomic position so that the remaining lung can expand completely. In general, however, it is best to keep the repair taut so as to optimize pulmonary mechanics after the procedure.

16 THORACIC DIAGNOSTIC AND STAGING PROCEDURES

Farzaneh Banki, MD and Larry R. Kaiser, MD, FACS

Thoracic diagnostic and staging procedures can be divided into those that involve the lungs, pleural space, mediastinum, and esophagus. Surgeons must be familiar with the TNM staging system for each major thoracic disease to decide on appropriate treatment. A general principle is to proceed with the diagnostic modality that will potentially yield or rule out the highest stage. As an example, in a patient with presumed non-small cell lung cancer and a pleural effusion, there is no reason to proceed with mediastinoscopy to assess lymph node involvement prior to interrogating the pleural space with video-assisted thoracoscopy (VATS). In this chapter, we review the diagnostic and staging procedures that relate to the most common thoracic malignancies that occur in the thoracic cavity that have relevance to the general surgeon.

Clinical Diagnosis and Staging

The diagnosis and staging of intrathoracic disease have major implications for treatment planning, especially in light of recent advances in both neoadjuvant and adjuvant treatment regimens in both lung cancer and esophageal cancer. These two malignancies account for the majority of the pathology seen within the chest cavity and treated by thoracic surgeons. TNM staging for both lung cancer and esophageal cancer recently has undergone revision as noted in the seventh edition of the American Joint Committee on Cancer (AJCC) cancer staging manual, effective since January 2010.¹ It is mandatory for every surgeon who treats these diseases to be intimately familiar with the staging classification as mentioned in the latest edition of this manual. The surgeon needs to be familiar with clinical staging based on preoperative imaging studies and pathologic staging that result from either preoperative invasive staging techniques or the findings that are generated by the pathologist who reviews the histology of the material obtained at the time of definitive resection. Optimal surgical resection that results in definitive information detailing the final clinical stage includes complete removal of the primary tumor as well as, ideally, a systematic dissection or, at minimum, sampling of the regional lymph nodes. Any procedure that is not this inclusive results in partial information that makes a decision regarding postoperative treatment significantly more difficult and may result in a poorer outcome for the patient.

Clinical staging of intrathoracic disease, specifically intrathoracic malignancies, relies on imaging modalities that range from plain chest radiography to positron emission tomography (PET). Most commonly, patients with intrathoracic complaints obtain a chest radiograph that may or may not delineate the relevant pathology. Computed tomographic

(CT) scans of the chest most commonly performed following the injection of intravenous contrast are the mainstay of thoracic imaging procedures. These scans are the most sensitive for defining parenchymal lung lesions and can detect lesions down to a size of several millimeters.

The appearance of a parenchymal lung nodule does not necessarily indicate malignancy. The only definitive information that can be obtained regarding a lung nodule seen on a CT scan is its size. There are no specific defining characteristics that are accurate in delineating a benign from a malignant nodule. If previous CT scans are available for comparison, an increase in the size of a nodule points toward malignancy but, again, is not definitive. The presence of a new nodule on a CT scan may mandate nothing more than a repeat scan in 3 months to assess whether the nodule is changing in size. An increase in the size of a nodule should mandate further diagnostic procedures to define the nodule. The size increase alone may be an indication for resection or, depending on the clinical setting, may mandate a needle aspiration biopsy to obtain material for cytologic analysis. However, one must be aware that only a positive result is helpful, as with any diagnostic test. A “negative” biopsy is of no use because a sampling error may account for the negative result and we are still faced with a nodule that has increased in size. Thus, prior to obtaining a needle aspiration biopsy, the surgeon should know how the information will be used. One recognizes intuitively that if the biopsy is positive for malignancy and there is no evidence of locally advanced or distant disease, the patient is a candidate for resection unless that option is precluded because of other underlying medical problems. But if operation is also indicated in the presence of a negative result on biopsy, one has to think seriously as to whether the risk of a needle biopsy is warranted.

CT scans are also excellent for demonstrating enlargement of mediastinal and hilar lymph nodes, but, once again, an increase in size alone does not necessarily translate into malignancy. By convention, we define mediastinal lymph nodes larger than 1 cm on short axis as pathologic, although some prefer to use 1.5 cm as the definition for pathologic.² Many surgeons have used CT scans to identify those patients without pathologic lymph nodes as defined by size criteria so that certain patients may proceed to resection without the need for invasive mediastinal staging. It has been reported that only 3 to 16% of patients with mediastinal lymph nodes less than 1 cm in size on a CT scan are found to have tumor involvement at mediastinoscopy.^{3,4} Sensitivity and specificity will vary depending on what size criteria for positivity one chooses to use. A meta-analysis looking at CT scans in assessing mediastinal lymph node involvement in bronchogenic carcinoma found an overall sensitivity and specificity of

79% and 78%, respectively.⁵ McLoud and colleagues reported even lower sensitivity and specificity of 64% and 62%, respectively.⁶ The bottom line here is that the presence of enlarged lymph nodes should prompt additional staging studies, including ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) PET and most likely mediastinoscopy to document the presence or absence of malignancy before deciding that a patient is not an operative candidate.⁷

PET is highly sensitive in the detection of mediastinal lymph node involvement in patients with bronchogenic carcinoma, with a lower limit of detection reported at 4 mm.⁸ It has been estimated to have a sensitivity as high as 91 to 96% and a specificity as high as 86 to 93% in staging of mediastinal lymph nodes.^{9–13} PET has also been found to be quite useful in differentiating benign from malignant parenchymal lung nodules. A nodule with positive ¹⁸F-FDG uptake on PET has a better than 90% likelihood of being malignant. Figure 1a demonstrates a right upper lobe nodule seen on a CT scan, whereas Figure 1b shows the same nodule on a PET scan. Increased metabolic activity is suggestive of malignancy, as seen in the hilar lymph node. The use of combined PET-CT is growing, and several studies suggest that the use of integrated PET-CT improves anatomic localization of lymph nodes compared with PET alone.¹¹ This study provides both the anatomic localization and size information when looking at the mediastinal lymph nodes, as well as the metabolic information obtained from the PET scan, which provides additional information useful in determining benign from malignant tumors. The same applies to parenchymal lesions.

Diagnostic and Staging Procedures for the Lungs, Pleura, and Mediastinum

BRONCHOSCOPY

Bronchoscopy is the standard diagnostic modality used for the assessment of disease that involves the airway, lungs, and pleura. The use of the fiberoptic bronchoscope has, for the most part, supplanted the use of rigid bronchoscopy for all but lesions thought to involve the trachea or proximal mainstem bronchi. It is safe, although sad, to say that rigid bronchoscopy is a dying art except for the few thoracic surgeons and interventional bronchoscopists who continue to use it for certain indications. Flexible bronchoscopes allow for visualization of the entire tracheobronchial tree out to the level of subsegmental bronchi, and lesions may be sampled via the working channel of the instrument. Techniques for sampling include brushings, washings, and use of a flexible biopsy forceps to obtain tissue samples. The procedure may easily be performed with the patient awake and lightly sedated with the instrument passed either via the nares or through the mouth using topical anesthetic to attenuate the gag reflex. Use of an endotracheal tube is not required to place the bronchoscope but may be used to secure the airway if necessary.

Once the instrument is passed, the vocal cords are visualized and traversed, with inspection then carried out of the entire airway. Topical anesthetic may be injected through the instrument as needed to prevent the patient from coughing. Orientation is secured by visualizing the origin of the right upper lobe bronchus, which is the most proximal orifice

Figure 1 (a) Right upper lobe non-small cell lung cancer on a computed tomographic scan. (b) Positron emission tomographic scan. The blue arrows indicate the primary tumor, and the red arrow indicates the hilar lymph node.

visualized when one proceeds beyond the carina and takes off at an acute angle [see *Figure 2*]. Proceeding down the right mainstem bronchus, the bronchus intermedius is entered distal to the right upper lobe takeoff, and the origin of the middle lobe and lower lobe bronchus can be seen. The takeoff of the superior segment of the lower lobe is visualized heading posteriorly. Next, the left main bronchus is entered and both upper and lower lobe bronchi are interrogated. Any endobronchial lesions seen may be sampled with the cup biopsy forceps. Parenchymal lesions may also be sampled via a transbronchial approach using fluoroscopy for precise localization of the biopsy forceps. Special alligator forceps are passed distally into the airway via the appropriate segmental bronchus, and either a discrete lesion or diffusely involved parenchyma may be sampled. Bleeding, if encountered, usually only requires saline lavage and tamponade with the

bronchoscope. Occasionally, epinephrine in saline is used to control bleeding after a transbronchial lung biopsy.

Transbronchial Needle Aspiration

Transbronchial needle aspiration (TBNA) is another diagnostic technique that may be used to assess regional lymph nodes and is performed via the flexible bronchoscope. A needle catheter is passed through the working channel of the instrument and guided to the area of the tracheobronchial tree adjacent to the mediastinal lymph node of interest. The needle catheter is advanced through the tracheal or carinal wall into the mediastinal lymph node, and a syringe is connected to aspirate cellular material. Several passes may be necessary until an adequate specimen is confirmed by the cytopathologist, who, ideally, is present. On-site cytopathologic examination of needle aspiration specimens significantly improves the yield of TBNA.

Figure 2 Diagrammatic representation of the right mainstem bronchus and the origin of the right upper lobe bronchus. Note the position of the upper lobe takeoff. This is the point of orientation for bronchoscopy. Reproduced with permission from Kaiser LR et al.²⁵

TBNA is used most frequently to assess subcarinal lymph nodes. Paratracheal lymph nodes may also be sampled with TBNA, but these are somewhat more difficult to access mainly because of the technical difficulty of sufficiently angulating the bronchoscope containing the needle catheter.¹⁴ It has been reported that it is feasible to obtain adequate specimens via TBNA in approximately 80 to 90% of cases.¹⁵ Results achieved for lymph nodes less than 1 to 1.5 cm may be substantially reduced but may improve up to 90% for nodes of greater than 1.5 cm.^{16–18}

Endobronchial Ultrasound-Guided Needle Aspiration

Endobronchial ultrasound-guided needle aspiration (EBUS-NA) is a procedure similar to conventional TBNA that also uses local anesthesia and sedation. However, the patient is intubated because of the larger external diameter of the EBUS-NA bronchoscope. EBUS-NA is a relatively new technique for mediastinal staging and employs a bronchoscope with a convex ultrasound probe that allows for real-time ultrasound-guided TBNA [see Figure 3]. EBUS-NA can be used to sample the highest mediastinal, upper and lower paratracheal, and subcarinal lymph nodes, as well as hilar lymph nodes. The overall reported sensitivity is 90%, with values ranging from 79 to 95%. The average reported false negative rate is 24% but varies significantly among reported series.^{19–21}

Rigid Bronchoscopy

Rigid bronchoscopy, when indicated, is performed with the patient anesthetized and in the supine position. The head should be placed in the “sniffing” position, and using the operator’s thumb as a fulcrum, the instrument tip is used to elevate the epiglottis. Once the vocal cords are visualized, the

instrument is turned so as to facilitate passage into the airway. The rigid instrument cannot be passed beyond the lobar level and is directed by turning the head. Rigid forceps may be used for sampling proximal lesions, and larger specimens may be obtained than can be using the flexible instrument. The rigid bronchoscope may also be used as a therapeutic tool to remove foreign bodies, dilate strictures, or debulk tumor that may be occluding proximal airways. It remains a very useful tool for those who have the expertise to use it.

MEDIASTINOSCOPY

This procedure remains the gold standard for assessing the status of the mediastinal lymph nodes whether for patients with a parenchymal lung lesion or for those who simply present with mediastinal adenopathy of unknown etiology. The CT scan of the chest is used to identify enlarged mediastinal lymph nodes, and the PET scan may be highly suggestive or even “definitive” that these nodes may harbor malignancy, but until there is histologic proof from tissue obtained, some doubt remains. Even with a positive PET scan, at least a 10 to 20% chance of a false positive result attributable mainly to inflammatory disease remains.

In 2007, Detterbeck and colleagues published evidence-based clinical practice guidelines for invasive mediastinal staging of lung cancer that concluded the following¹⁴:

1. In patients with discrete mediastinal nodal enlargement, staging by CT or PET scan is not sufficiently accurate. The sensitivity of various techniques is similar in this setting, although the false negative rate of needle techniques is higher than that for mediastinoscopy.
2. In patients with a stage II or central tumor, invasive staging of the mediastinal nodes is necessary.

Figure 3 (a) Endobronchial ultrasound probe with the inflated balloon. (b) Ultrasound image with the tip of the needle in the mediastinal lymph node. Reproduced with permission from Yasufuku K et al.²⁰

3. Mediastinoscopy is generally preferable because of the higher false negative rates of needle techniques in the setting of normal-sized lymph nodes.
4. Patients with a peripheral clinical stage I non-small cell lung cancer do not usually need invasive confirmation of mediastinal nodes unless a PET scan finding is positive in the nodes.
5. The staging of patients with left upper lobe tumors should include an assessment of the aortopulmonary window lymph nodes.

Mediastinoscopy is performed with the patient under general anesthesia and positioned supine with the neck hyperextended. A small cervical incision is made approximately 2 cm above the sternal notch, and the strap muscles are separated in the midline. The pretracheal fascia is incised, and the mediastinal plane is defined with finger dissection [see Figure 4]. In most patients, the carina may be palpated with the back of the finger at the distal extent of the defined plane. The innominate artery is palpated anteriorly, as is the arch of the aorta. Thus, the mediastinoscope is passed in a plane with the trachea immediately posterior and the brachiocephalic vessels immediately anterior. Both the right and left upper and lower paratracheal nodal locations may be accessed, as well as the subcarinal space. The mediastinoscope is passed posterior to the right main pulmonary artery as the artery traverses the carina. Recognizing the major vascular structures that are within the field, the operator can see the potential for causing havoc if he or she is not intimately familiar with the performance of this diagnostic procedure [see Figure 5]. Mediastinoscopy is not for the occasional operator; it is a difficult procedure to teach and difficult to perform well. The advent of the video-assisted mediastinoscope has helped advance the teaching of the technique.

It is difficult to overestimate the value of this procedure and the significance of the information in guiding therapy, especially for patients with non-small cell lung cancer. The presence of ipsilateral nodal, or N2, disease portends a somewhat dismal prognosis but also indicates the need for multimodality therapy to achieve optimal results. If at the time of mediastinoscopy, contralateral nodal, or N3, disease is found, this rules out the possibility of surgical resection adding anything to the overall outcome and the patient is, in most circumstances, considered inoperable. The finding of contralateral nodal disease is most common with tumors that arise in the left lower lobe.

This points out the importance of performing a complete and thorough examination of the mediastinum with appropriate specimens taken. This includes sampling the right upper and lower paratracheal locations (levels 2 and 4), left lower paratracheal locatoin (level 4; it is unusual to find upper paratracheal nodes on the left, likely because of the position of the aortic arch), and the subcarinal space (level 7) [see Figure 6]. Finding left level 4 lymph nodes can be challenging, especially for the inexperienced operator, and exploration in this location puts the left recurrent nerve at risk. Complete sampling is not required if contralateral nodal disease is identified first or for those patients who present simply with mediastinal adenopathy but without a lung lesion where the differential diagnosis includes malignancy, sarcoidosis, and other inflammatory or infectious disease. In the latter situations,

a single sample from the most easily accessible location suffices, but adequate tissue for diagnosis must be confirmed by the pathologist on frozen section at the time of the procedure prior to terminating the operation.

The possibility of a major injury to the azygos vein, innominate artery, or pulmonary artery is very real if the surgeon should inadvertently attempt to obtain a specimen from what appears to be a lymph node but is actually a vessel. Often the azygos vein looks very much like an enlarged lymph node, but palpation with the suction or cautery gives the tactile sense of something other than a solid structure. The development of this tactile sense often comes only with significant experience with this procedure. Injury to a vessel may also occur if a lymph node is adherent, unbeknownst to the surgeon, who encounters significant bleeding after sampling a node.

Anyone performing this procedure should know how to manage a potentially lethal complication should a major vascular injury occur. The initial maneuver should be to tamponade the bleeding either with a finger or preferably by packing. Vaginal packing should be on the field just for such use. Only if the bleeding appears minimal should any attempt be made to control it through the mediastinoscopy with clips or electrocautery. Bleeding is common following sampling of the subcarinal space and is easily controlled with minimal packing. When the bleeding is such that the field becomes dark, it is time to pack the mediastinum and prepare for median sternotomy. Once the bleeding has been stopped by packing, the anesthesiologist should have blood in the room and fluids given to optimize perfusion while preparations are made for median sternotomy. The sternotomy approach allows access to any potential bleeding site and because the patient already is supine obviates the need to turn the patient to the lateral decubitus position. The azygos vein is also accessible and can be controlled via this approach as well.

Also vulnerable to injury during mediastinoscopy, as discussed above, is the left recurrent laryngeal nerve. This can be injured with electrocautery if used too close to the nerve or by the biopsy forceps. Unfortunately, this is an all too common complication that results in significant morbidity. The hoarseness or breathy voice that results is one issue, but the major one is the possibility of aspiration on swallowing that can result because of the incomplete glottic closure that is a consequence of the left vocal cord being in the abducted position.

PARASTERNAL MEDIASTINOTOMY

This procedure is related to mediastinoscopy but usually does not require the use of a mediastinoscope. Originally referred to as a Chamberlain procedure, this technique was formerly used most commonly to sample enlarged lymph nodes (level 5) located in the aortopulmonary window on the left side. Currently, most surgeons employ VATS to sample that area if indicated to make a treatment decision. This procedure is most commonly used to obtain tissue from an anterior mediastinal mass to establish a diagnosis. The most common lesion to occur in this location is a lymphoma, either Hodgkin disease or non-Hodgkin lymphoma. Adequate tissue is necessary not only to establish a diagnosis but also to aid in typing the lymphoma. As mentioned above, the procedure most commonly is performed on the left side but may also be

Figure 4 Development of the mediastinal plane prior to introducing the mediastinoscope. (a, b) Oblique and anterior views of the finger entering the pretracheal space after the fascia has been incised. The finger goes along the anterior aspect of the trachea, and the innominate artery is palpated anteriorly. (c) The finger is passed beyond the innominate artery, and both the right and left paratracheal areas are palpated. (d) The finger now is at the level of the carina, which, in most cases, can be palpated. The mediastinal space is now ready for insertion of the mediastinoscope. Reproduced with permission from Kaiser LR et al.²⁵

Figure 5 Schematic representation of blood vessels in the superior mediastinum also showing the location of lymph nodes at the tracheobronchial angle. The mediastinoscope is inserted into this space, anterior to the trachea and posterior to the innominate artery. The trachea is always the reference point for location during the conduct of the procedure. Reproduced with permission from Mentzer SJ.²⁶

Figure 6 View as seen through the mediastinoscope of the carina and subcarinal space. Note the location of the right main pulmonary artery as it traverses the carina and its proximity to the subcarinal space. Note also the location of the azygos vein. Reproduced with permission from Mentzer SJ.²⁶

carried out on the right side depending on the location of the anterior mediastinal mass.

A small incision is made over the second rib cartilage immediately adjacent to the sternum [see Figure 7]. Resecting the second costal cartilage in a subperichondrial plane

facilitates entry into the mediastinum without breaching the pleural reflection. Some surgeons choose not to resect the costal cartilage and either attempt to stay out of the pleural space or routinely enter it. In any case, care must be taken to avoid the internal thoracic artery pedicle, which usually may

Figure 7 Diagrammatic representation of a left anterior mediastinotomy. (a) An incision is made immediately adjacent to the sternum over the left second costal cartilage. (b) The second costal cartilage is removed, allowing access to the mediastinum without entering the pleural space, or the pleura may be incised. Note the location of the internal mammary vessels. (c) Enlarged lymph nodes in the aortopulmonary window. Reproduced with permission from Kaiser LR et al.²⁵

be identified and reflected out of the way. The endothoracic fascia is incised, the pleural reflection is swept laterally, and the mass is encountered. Multiple samples of the mass may be taken with a biopsy forceps, and frozen section will determine if adequate material has been obtained. If the pleural space is entered, simply placing a red rubber catheter prior to closure and removing it just prior to skin closure following a Valsalva maneuver removes any air from the pleural space. Given that there is no ongoing air leak from lung parenchyma, this is all that is required. Some have warned of the possibility of “seeding” the pleural space when sampling what turns out to be a thymoma, but staying out of the pleural space renders that concern moot.

VIDEO-ASSISTED THORACIC SURGERY

There are multiple uses for VATS procedures in the diagnosis and staging of intrathoracic pathology. As mentioned above, its use for mediastinal staging, for the most part, is confined to accessing the aortopulmonary window to sample the level 5 lymph nodes, if indicated [see Figure 8]. By far the most common use is to assess the pleural space, especially when a pleural effusion is present and there is a question of pleural involvement. Not all pleural effusions indicate pleural space involvement by tumor. In a patient who presents with a pleural effusion for which there is no plausible explanation, thoracentesis is first performed. If positive, the patient is staged M1a and no further invasive diagnostic or staging procedure is necessary. If negative and the patient has a

parenchymal lung lesion, a VATS procedure may be performed to visually examine the parietal and visceral pleural surfaces and sample any abnormal areas seen. Not all malignancies that involve the pleura will shed cells; thus, false negative thoracenteses are not uncommon, especially with certain histologies. If the VATS procedure fails to detect any pleural involvement, then resection can proceed assuming that there is no other evidence of metastatic disease.

In addition to the diagnosis of pleural involvement, VATS has been used routinely to resect parenchymal nodules for diagnosis prior to proceeding with resection. A wedge excision of a pulmonary nodule confirms the diagnosis prior to proceeding with lobectomy, and resection may then be carried out completely via VATS or open thoracotomy. Finding a benign nodule saves the patient a lobectomy and the attendant morbidity. In addition, VATS has been particularly useful in obtaining lung parenchyma in those patients with diffuse interstitial lung disease where a diagnosis guides therapy. For interstitial disease, samples are taken from at least two locations, ideally in different lobes, to fully assess the process. Most commonly, VATS is performed with three incisions placed in a triangulated fashion, which allows for the scope to be placed in one port, leaving the other two for instrument placement. Thus, the lung parenchyma may be grasped via one port and an endoscopic stapler placed in the other to perform the excision. The presence of diagnostic material should be confirmed by the pathologist prior to terminating the procedure.

Figure 8 Video-assisted thoracoscopic view of the aortopulmonary window. The third and seventh intercostal space access ports are placed. The lung is reflected posteriorly. The phrenic nerve is traced to the level 6 lymph nodes at the base of the innominate artery. The arrows show the level 5 aortopulmonary window and level 6 para-aortic lymph nodes. Reproduced with permission from Mentzer SJ.²⁶

MEDIASTINAL LYMPH NODE DISSECTION: CRITICAL TO A COMPLETE OPERATION FOR LUNG CANCER

An anatomic pulmonary resection, in most cases lobectomy, remains the standard and definitive operation for lung cancer. As part of the standard operation, a systematic lymph node dissection or, at minimum, lymph node sampling should be performed in all cases to gain maximal information regarding staging. The optimal lymph node dissection consists of excision and examination of mediastinal, hilar, and lobar lymph nodes in a systematic fashion as defined at an international workshop held in 1996 and supported by the International Association for the Study of Lung Cancer. Hilar and lobar lymph nodes are removed with the lobectomy specimen, whereas a separate procedure is required to either sample or systematically dissect the mediastinal lymph nodes. On the right side, the superior mediastinal lymph node packet is defined anteriorly by the superior vena cava, posteriorly by the trachea, superiorly by the subclavian artery, and inferiorly by the azygos vein. In addition, the entire contents of the subcarinal space are taken. On the left side, there is no well-defined lymph node packet, but nodes are removed from the aortopulmonary window and periaortic position as well as from the subcarinal space. The lower paratracheal nodes (left level 4) may also be removed by dissecting inferiorly to the aortic arch, but care must be taken to avoid damage to the left recurrent laryngeal nerve. Because of the difficulty in accessing the left lower paratracheal lymph nodes, there should be a low threshold for performing mediastinoscopy for left lung lesions if there is any suspicion of lymph node involvement based on preoperative imaging studies. There is no definitive evidence that mediastinal lymph node dissection is a therapeutic procedure, but there is no question that it provides the most accurate staging information. Improved survival has been associated with the number of lymph nodes removed, with 11 to 16 being the optimal number.²²

Diagnostic and Staging Procedures for the Esophagus

ESOPHAGOSCOPY

For presumed structural lesions of the esophagus, flexible esophagoscopy is the procedure of choice. Topical anesthetic for the pharynx with minimal intravenous sedation is all that is necessary for this examination. The patient is placed in the left lateral decubitus position, with the tip of the instrument placed posterior to the tongue, and is asked to swallow to allow passage through the cricopharyngeus. Once beyond that point and aided by insufflation, the lumen of the esophagus is easily visualized to facilitate passage of the instrument into the stomach. The pylorus is observed, and the endoscope is passed into the duodenum. The major part of the examination is carried out as the instrument is withdrawn. The entire stomach is examined, and the endoscope is retroflexed to examine the gastroesophageal junction. Continued withdrawal into the esophagus allows for complete visualization back up to the cricopharyngeus. Flexible biopsy forceps are available to be passed through the working channel if a lesion is seen, and multiple samples may need to be taken because of the small cup size of the forceps.

A specialized dedicated endoscope equipped with an ultrasound probe allows the operator to visualize the depth of

invasion of an esophageal tumor as well as provide a look at the regional lymph nodes. The esophageal wall is able to be visualized as a five-layered structure, and the T stage assessed by endoscopic ultrasonography is approximately 80% accurate when compared with the ultimate pathologic stage. The ultrasound signal obtained from an involved lymph node may be diagnostic and provides information that guides a treatment decision, specifically the need for preoperative chemotherapy with or without radiation therapy. Endosonographic criteria most specific for malignancy are an echo-poor pattern and width greater than 10 mm. The sensitivity and specificity for detecting celiac lymph node metastases were 85% (95% CI 72 to 99) and 96% (95% CI 92 to 100), respectively. Sensitivity and specificity for other regional lymph node metastases were 80% (95% CI 75 to 84) and 70% (95% CI 65 to 75), respectively.²³

To further improve the diagnostic capability of endoscopic ultrasonography, fine-needle aspiration (EUS-FNA) of visualized lymph nodes may be performed. The sensitivity, specificity, and accuracy of EUS-FNA for locoregional lymph nodes are all over 85%.²⁴

The use of the rigid esophagoscope is confined to the diagnosis of proximal esophageal neoplasms and has no role in staging. This instrument provides a large working channel and allows for the use of a rigid biopsy forceps that enables the collection of large tissue fragments for histologic analysis. The rigid instrument is a skill that must be learned to pass the instrument safely. If not passed correctly, the rigid instrument can perforate the cervical esophagus. Like the rigid bronchoscope, the thumb is used as a fulcrum on which the instrument rests and the cricopharyngeus is visualized by lifting anteriorly. Once the lumen is seen, the instrument is passed and advanced. With the longer instruments, the entire esophagus may be visualized down to the level of the gastroesophageal junction, but the primary area of interest is the proximal esophagus.

Conclusion

The evaluation of a patient who presents with a question of intrathoracic pathology should begin with appropriate imaging studies, usually beginning with plain chest radiography followed by CT scanning of the chest done with intravenous contrast. Comparison with a previous film may be all that is necessary to avoid further testing if the lesion in question was present on the old film and remains unchanged. Following appropriate imaging that may include a PET scan, a decision needs to be made as to which diagnostic procedure should be performed. Bronchoscopy is the procedure of choice for the diagnosis and staging of pulmonary pathology, and endobronchial as well as transbronchial sampling of tissue may be carried out with this instrument. Staging procedures need to be done in a thoughtful and systematic manner because accurate staging has prognostic implications in patients with lung cancer and guides both initial and subsequent therapy. When these imaging modalities indicate suspicion for mediastinal lymph node involvement, such as an enlarged mediastinal lymph node (> 1 cm) on a CT scan or increased ¹⁸F-FDG uptake in mediastinal lymph nodes on a PET scan (standard uptake value > 2.5) or evidence of distant organ metastasis, tissue biopsy is required for accurate

staging. In the absence of suspicious mediastinal lymph nodes on imaging studies, the choice of diagnostic procedures depends on the location and size of the tumor and the presence of abnormal hilar lymph nodes (N1 disease), a finding that is associated with a higher likelihood of mediastinal nodal involvement.

The classic technique for staging of mediastinal lymph nodes has been standard cervical mediastinoscopy, which allows inspection and sampling of bilateral paratracheal locations and the subcarinal space. Transtracheal needle aspiration of suspicious mediastinal lymph nodes may be carried out through the bronchoscope, but in the presence of abnormal lymph nodes on imaging studies, a negative needle aspiration biopsy should lead to mediastinoscopy (for levels 2, 4, and 7) to ensure that the result was not a false negative. Decisions regarding operability or resectability should not be based solely on abnormalities seen on imaging studies. Pathologic confirmation based on tissue sampling should be the gold standard and offers the patient the best opportunity for a favorable outcome. A systematic mediastinal lymph node dissection should be part of every resection for primary lung cancer. Without the information gained from a node dissection or, at minimum, systematic sampling, staging is

incomplete, and this could result in the patient being overtreated. Although not conclusive, there may also be a therapeutic benefit to mediastinal lymph node dissection.

Unexplained pleural effusions should be evaluated using VATS to assess the pleural surfaces if thoracentesis yields a negative result. VATS may also be used for the diagnosis of either diffuse interstitial lung disease or discrete pulmonary nodules. Assessment of lymph nodes present in the aortopulmonary window on the left side may also be successfully carried out using VATS.

Esophageal pathology is assessed and staged with the flexible esophagoscope and endoscopic ultrasonography. In addition to imaging studies, esophageal motility studies and 24-hour pH monitoring are used to assess benign esophageal pathology, specifically motor disorders.

The surgeon who deals with intrathoracic pathology must be facile with all of the modalities available for diagnosis and staging and should proceed in a logical sequence so that sufficient information is gathered to allow appropriate decision making regarding treatment.

17 THORACIC OUTLET SYNDROME

Mark W. Fugate, MD, and Julie A. Freischlag, MD

Thoracic outlet syndrome (TOS) is a condition caused by compression of the neurovascular structures leading to the arm passing through the thoracic outlet. The incidence of TOS is reported as 0.3 to 2% in the general population.¹ There are three distinct types of TOS: neurogenic (95%), venous (4%), and arterial (1%). Treatment algorithms depend on the type of TOS. Arterial and venous TOS often present urgently with arterial or venous thrombosis, which is fairly easily identified by thorough history taking and a physical examination. Diagnosis is also aided by duplex ultrasonography. Restoration of arterial or venous flow can often be readily accomplished by thrombolysis. More important, however, is the diagnosis of the underlying structural component involved in the development of symptoms. Although statistically the most common, neurogenic TOS is often the most difficult to diagnose and treat. There are good data indicating that appropriately selected patients benefit from surgical therapy for neurogenic TOS as well. To prevent recurrence of symptoms, patients must undergo first rib resection and anterior scalenectomy, as well as resection of any rudimentary or cervical ribs. Regardless of the type of TOS encountered, proper therapy requires a thorough diagnostic evaluation and multidimodal treatment.

History

Historically, TOS has been a controversial syndrome in terms of its causes, diagnosis, and management. Galen first described a cervical rib in human cadaver dissections.² As his work had fallen out of favor during the Dark Ages, Vesalius, who revived much of Galen's work, again described the cervical rib among human cadavers.² In 1821, Sir Astley Cooper observed that a subclavian artery occlusion was caused by compression from a cervical rib, which came to be known as cervical rib syndrome.³ In 1927, the first rib was implicated in neurogenic TOS.⁴ In 1935, Ochsner and colleagues described the scalenus anticus syndrome, and an association was first made with trauma.⁵ Compression of the subclavian artery and vein was termed costoclavicular syndrome in 1943.⁶ The term thoracic outlet syndrome was first introduced in 1956 by Peet and colleagues, who also described a therapeutic exercise regimen in the management of the syndrome.⁷ This was an important contribution as physical therapy continues to be one of the mainstays of therapy for neurogenic TOS.

As the views of the anatomic causes of TOS evolved over the years, so did the surgical approaches to its management. In 1861, Coote completed the first successful cervical rib resection for relief of arterial compression.⁸ Murphy performed a first rib resection in 1910 for neurogenic TOS.⁹ Adson and Coffey performed the first scalenectomy in 1927, without first rib resection.¹⁰ Later, it was realized that the

division of the muscle alone led to recurrent symptoms. The posterior approach to first rib resection was described by Clagett in 1962,¹¹ and the transaxillary approach to first rib resection was described by Roos in 1966.¹² Other surgical approaches include supraclavicular as well as combined techniques using transaxillary first rib resection and transcervical scalenectomy.^{1,13}

Anatomy and Predisposing Factors

TOS is divided into three distinct subtypes: neurogenic, venous, and arterial. Symptoms are produced relative to which of the neurovascular structures is compressed in the thoracic outlet [see Table 1]. In this regard, the scalene triangle is the most important anatomic space in the thoracic outlet. The anterior and middle scalene muscles comprise the sides of the scalene triangle, with the first rib forming the base of the triangle. The anterior and middle scalene both arise from the lower cervical spine. Through this relatively small space pass the subclavian artery and vein, as well as the five nerve roots of the brachial plexus. These muscles can potentially scar and/or hypertrophy with repetitive motion or trauma, further contributing to compression of the neurovascular structures. The subclavius muscle, which is found between the clavicle and the first rib, also may compress the subclavian vein, contributing to venous TOS. This muscle is frequently found to be hypertrophied in patients presenting with effort thrombosis.¹⁴

A combination of congenital anatomic predispositions and acquired extrinsic factors results in the spectrum of symptoms associated with TOS. Cervical ribs, which are congenital, can predispose to all three types of TOS. They have an incidence of approximately 1% in the general population with 50% bilaterality.^{15,16} Although most cervical ribs are asymptomatic, they occur in up to 11% of patients undergoing surgical decompression for TOS.^{17,18} A long C7 transverse process or bifid first rib may also predispose to TOS, but these are even less common. Particularly in neurogenic TOS, congenital fibromuscular bands often are observed—in more than 80% of patients, according to some authors.¹⁹ These congenital bands and ligaments have been categorized into nine different types by Roos.²⁰ Anatomic variation in the size and insertion points of the scalene muscles has also been implicated.

In addition to these predisposing anatomic factors, trauma and repetitive motion also play a role in the development of TOS. Some authors have reported that up to 80% of TOS patients have a history of trauma to the neck or shoulder area.²¹ Repetitive motion attributable to athletic activity (e.g., swimming or weight lifting) or occupational environment (e.g., poor posture and/or prolonged computer use) also may contribute to the development of TOS.

Table 1 Thoracic Outlet Syndrome: Types and Characteristics

Characteristic	Neurogenic Most Common Form of TOS	Venous Subclavian Vein Thrombosis	Arterial Subclavian Artery Thrombosis
Sex	Female (3.5:1)	Male	Female/male equally
Age (yr)	20–40	20–30	20–30
Risk factors	Repetitive movements Previous trauma	Strenuous work Athletics	Vigorous arm activity
Symptoms	Pain down arm, forearm, ring finger, and little finger Paresthesias (pain, numbness) at night Arm/hand weakness Arm/hand swelling Loss of dexterity Cold intolerance Headache	Pain in affected arm often associated with strenuous work Arm/hand swelling Veins of shoulder and chest appear more visible Hand/arm appears blue in color	Pain Claudication Hand appears white in color Hand/arm cool Decreased pulse
Laboratory studies	None	Hypercoagulable studies	Hypercoagulable studies
Imaging studies	Chest x-ray	Chest x-ray Duplex ultrasonography Venography	Chest x-ray Duplex ultrasonography Arteriography
Other studies	Nerve conduction study	Nerve conduction study	Nerve conduction study
Consultations	Vascular surgeon Physical therapy (PT) Pain management	Vascular surgeon Hematologist	Vascular surgeon Hematologist
Treatment	Physical therapy (PT) Lidocaine blocks Botulinum toxin blocks* Surgical intervention† Postoperative PT	Anticoagulant Surgical intervention Venography/venoplasty Postoperative PT	Anticoagulant Surgical intervention Arteriography/arterioplasty Postoperative PT
Prognosis	Good	Good	Good
Recovery time	Longer period of time (time needed is dependent on duration of symptoms prior to treatment and commitment to PT)	Quick	Quick

TOS = thoracic outlet syndrome.

†Not all neurogenic TOS patients need or are candidates for surgery.

Preoperative Evaluation

NEUROGENIC THORACIC OUTLET SYNDROME

Symptoms attributable to neurogenic TOS are caused by compression of the roots of the brachial plexus and are much the same as those experienced with nerve compression in other parts of the body. Pain, paresthesias, and weakness in the pattern of the affected nerve roots are common. Pain and/or point tenderness in the anterior or posterior shoulder region, as well as the neck and occipital or mastoid region, is also a common finding. Headaches may also be present. On physical examination, there is often tenderness over the scalene muscles and/or the supraclavicular fossa on the involved side. Radiation of pain or paresthesias in the symptomatic arm can often be reproduced by deep palpation of the scalene muscles or other provocative maneuvers, such as abducting the arms to 90° in external rotation. With the arms in the same position, the patient can be asked to repeatedly open and close the hands for several minutes, the so-called Roos stress test. Reproduction of the patient's symptoms with this maneuver may be an indication of neurogenic TOS. During the Adson maneuver, the arm on the affected side is

abducted and the head is rotated toward the same side. Disappearance of the radial pulse is a nonspecific finding, but reproduction of the patient's symptoms may again be an indication of neurogenic TOS. Decreased grip strength and mild to moderate sensory abnormalities in the affected hand are common findings. Atrophy of the intrinsic muscles of the hand is a late and uncommon finding. A chest x-ray to rule out bony abnormalities is mandatory. Magnetic resonance imaging, nerve conduction studies, and electromyography can be helpful. However, as there is no definitive diagnostic test for neurogenic TOS, the diagnosis is typically clinical. Prior to considering surgery for neurogenic TOS, nerve conduction studies should be obtained as they are the best objective test for this condition.

VENOUS THORACIC OUTLET SYNDROME

The most common presentation of venous TOS is acute effort thrombosis of the axillosubclavian vein, also known as Paget-Schroetter syndrome. This is characterized by the sudden onset of swelling, pain, and discoloration of the affected upper extremity. Edema is nonpitting and involves the entire arm. Additionally, superficial veins of the upper

arm, shoulder, and chest wall may be distended and visible. Typically, these patients are young and healthy and often quite athletic. Swimmers, weight lifters, and volleyball players are particularly common. Again, the diagnosis is typically clinical but can be confirmed with duplex ultrasonography. If ultrasonography is for some reason unavailable or equivocal, contrast venography will confirm the diagnosis. Again, chest x-ray to rule out bony abnormalities should be performed.

ARTERIAL THORACIC OUTLET SYNDROME

Symptoms attributable to arterial TOS are commonly the result of thromboemboli from intimal lesions or post-stenotic arterial aneurysms. Patients present with varying degrees of arm or hand ischemia. Ischemia may manifest with many signs and symptoms, including weakness, paresthesias, pain and pallor, and diminished pulses distally, especially with activity or positional changes. A positive Adson test aids in the diagnosis but is not pathognomonic. Chest x-ray is extremely important in the diagnosis as cervical ribs are often present in cases of arterial TOS. Duplex ultrasonography is also essential to assess the presence and degree of arterial stenosis and to detect subclavian artery aneurysm.²² Arteriography is not mandatory but can be quite useful in identifying arterial lesions caused by extrinsic compression or post-stenotic aneurysms.

Treatment

NEUROGENIC THORACIC OUTLET SYNDROME

Initial therapy for neurogenic TOS is always conservative. This consists of two broad categories, lifestyle modification and physical therapy. Lifestyle modification includes posture training for proper posture when walking, sitting, and standing, which promotes relaxation of the neck muscles and may help decompress the thoracic outlet. It also includes modification of daily activities, including minimization of repetitive motion, overhead work, and weight lifting, if applicable. Exercises directed toward improved range of motion and flexibility also may provide symptomatic improvement. Physical therapy is TOS specific [see Table 2] and consists of three sessions per week for 8 weeks before surgery is considered. If the patient proceeds to surgical treatment, physical therapy is also used postoperatively for the same frequency and duration to include increased range of motion, strengthening exercises, and soft tissue or scar tissue massage.

If lifestyle modification and physical therapy are unsuccessful, a computed tomography (CT)-guided anterior scalene block is performed with local anesthetic. The block causes relaxation of the anterior scalene muscle, allowing the first rib to drop, which should relieve tension on the brachial plexus. Symptomatic relief as the result of a scalene muscle block is a reasonable procedure to give some indication as to whether a first rib resection and anterior scalenectomy will be beneficial. CT-guided scalene muscle block is used by some investigators for diagnosing neurogenic TOS.²³ We have also found that CT-guided botulinum toxin type A (Botox, Allergan, Irvine, CA) injections provide symptomatic relief for at least 1 month and often up to 3 months.²⁴ These treatments may be used as a bridge to surgery or as an adjunct to nonoperative treatment with physical therapy. We do not offer more

Table 2 Thoracic Outlet Syndrome: Specific Physical Therapy Protocol

Weeks 1–3 Manual therapy: - Soft tissue mobilization (STM) of scar when closed - STM of anterior thorax, intercostal spaces, diaphragm - Joint mobilization of sternoclavicular (SC) and costosternal joints and acromioclavicular joint (AC) - Positioning and mobility of the ribs - Mobilization of the thoracic and cervical spine - Usually thoracic extension and cervical flexion - Focus of occiput-atlantis (OA) flexion - Brachial plexus and peripheral neural mobility - Teasing stretch or pain sensation—with caution to avoid exacerbating symptoms Therapeutic exercise and neuromuscular reeducation: - Diaphragmatic breathing - OA flexion - Gentle scapular posterior depression exercises - Use prolonged holds > 45" to retain position and movement with gentle manual resistance - Gentle neural mobility Posture training: - Activity restriction education, patient self-care education - Sleep position and transfers - Lifting and reaching related to activities of daily living (ADL)
Weeks 4–6 (build-off gains made in weeks 1–3) Manual therapy: - STM to pectoralis, serratus anterior, and latissimus dorsi - STM to neck and along track of brachial plexus (neck to hand) - Gentle mobility of glenohumeral joint and AC joint separation - Focus on inferior glide of humeral head and mobility of the posterior rotator cuff Therapeutic exercise and neuromuscular reeducation: - Continue with prolonged holds of OA flexion with manual and self-progressive resistance exercise - Continue with prolonged holds of scapular posterior depression - Add mild resistance with Thera-Band or weights - Train scapular stability in prone or elbow position before progressing to quadruped - Supine shoulder flexion exercises with wand - Add gentle manual resistance in flexion when patient can perform full flexion without scapular substitution, thoracic extension, or sternum elevation Posture training - Focus on sitting posture and assumption of work position while holding proper posture
Weeks 7–8 Manual therapy: - Moderate to aggressive glenohumeral mobilizations (specifically Mulligan glenohumeral mobilizations with movement) - Continue neural mobilization until patient can reach full tension position without complaints of pain/stretch symptoms - Address other limitations in soft tissue and joint mobility as needed Therapeutic exercise and neuromuscular reeducation: - Scapular posterior depression exercises against resistance as tolerated - Still focus on prolonged hold of postural muscles - Plank exercises maintaining scapular neutral position - Add weight shifts, walking out with a Thera-Ball, and pushups from the knees - Independent maintenance of neural mobility - Progress to resisted exercises of shoulder flexion against gravity if patient is able to perform without scapular substitution - Perform exercises until fatigue or substitution Posture training: - Lifting crates/boxes with full squat while maintaining scapular neutral position - Mimic work-related activities

than two injections because the muscle and surrounding tissues tend to scar and the long-term effects of repeated botulinum toxin injections are not known.

Surgical treatment consists of first rib resection and anterior scalenectomy, and our favored approach is transaxillary (see below). When neurogenic TOS patients are appropriately selected for surgical intervention, we have shown good outcomes in terms of quality-of-life improvements.²⁵

VENOUS THORACIC OUTLET SYNDROME

Traditionally, treatment of secondary axillosubclavian vein thrombosis has consisted of conservative measures: systemic anticoagulation with rest and elevation of the affected extremity. However, in primary axillosubclavian vein thrombosis, conservative treatment alone leaves most patients with residual symptoms attributable to venous outflow obstruction. As most of these patients are young and active, more aggressive therapy is required. Once the diagnosis of thrombosis as a result of venous TOS is suspected, the patient should undergo contrast venography. Once thrombosis is confirmed, catheter-directed thrombolysis should be performed. Once the thrombosis has been cleared, venography should be repeated to confirm extrinsic compression of the subclavian vein. Compression and narrowing of the vein at the costoclavicular junction are almost universally present in cases of venous TOS. Angioplasty and stenting should not be performed in the initial setting until the patient has undergone thoracic outlet decompression via first rib resection and anterior scalenectomy. This can be performed days to weeks after the initial thrombolysis. Again, our preferred approach is transaxillary. To avoid bleeding complications, no anticoagulation is given until 3 days after surgery. Therapeutic low-molecular-weight heparin injections are given until 2 weeks later, when repeat venography is performed. At this time, residual stenotic areas can be percutaneous and dilated effectively as extrinsic compression has been relieved. If the vein has remained patent and no intervention is required, anticoagulation is discontinued. If the vein has rethrombosed, repeat thrombolysis may be performed and anticoagulation continued with warfarin, with an international normalized ratio of 2 to 3. The patient is followed long term with duplex ultrasonography monthly, and anticoagulation is continued as long as areas of increased velocities in the subclavian vein are visualized during arm abduction, up to 6 months. In our series of more than 80 patients with venous thrombosis secondary to venous TOS, we found that after 6 months, all remained patent. Therefore, we do not anticoagulate beyond this time.

The final important consideration is a thorough hypercoagulable workup. We have observed an increased frequency of hypercoagulable disorders in patients with Paget-Schroetter syndrome. Therefore, we now perform a hypercoagulable workup in all our venous TOS patients, as well as in arterial thrombosis patients. If the patient presents acutely, these laboratory values will be assessed initially. If the patient presents from another institution where he or she has already undergone thrombolysis and is being maintained on warfarin therapy, the hypercoagulable evaluation is done 6 months after discontinuation of warfarin. These laboratory tests include protein C and S levels, factor V Leiden mutation, prothrombin gene mutation 20210, antithrombin III level,

antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies), homocysteine levels, and methylene tetrahydrofolate reductase (MTHFR) 677T variant. If the patient is confirmed to have a hypercoagulable disorder, then he or she is continued on lifelong anticoagulation.

ARTERIAL THORACIC OUTLET SYNDROME

The timing and sequence of therapy for arterial TOS depend on the degree and acuteness of ischemia. The majority of patients with arterial TOS present chronic ischemic symptoms and a nonthreatened limb. In this situation, the proximal embolic source is eliminated first. This is typically accomplished by direct arterial reconstruction, preferably with an autologous vein. This can be undertaken at the same time of resection of the commonly found cervical or rudimentary rib, depending on the surgical approach. In arterial TOS, a transaxillary approach may be employed for rib resection and scalenectomy, but arterial reconstruction is not possible from this approach. This typically requires a supraclavicular approach. If the patient presents with acute and limb-threatening ischemia, distal thromboemboli must be cleared first, either surgically or via thrombolysis, before rib resection and arterial reconstruction.

TRANSAXILLARY APPROACH TO FIRST RIB RESECTION AND ANTERIOR SCALENECTOMY

A detailed description of the multiple approaches to thoracic outlet decompression is beyond the scope of this chapter. Our preferred approach is transaxillary because it allows for safe exposure and excellent visualization of the major structures through a cosmetically acceptable, low-morbidity incision. First and cervical ribs, as well as rudimentary ribs, are all readily removed via this approach. The vast majority of patients are easily treated through transaxillary thoracic outlet decompression. As previously mentioned, direct arterial reconstruction is the only task not amenable to this technique.

The patient undergoes general anesthesia with a short-acting neuromuscular blockade such as succinylcholine, allowing for safer dissection around the brachial plexus, as well as easier identification of the long thoracic nerve. The patient is placed in the lateral decubitus position and prepared from the neck to beyond the nipples. An adjustable arm support, the Machleder retractor [see Figure 1], is attached to the operating room table and allows for elevation of the arm. This elevation is vital for adequate exposure of the axilla during dissection. Prior to placement on the retractor, the arm is well padded to prevent injury to the median and ulnar nerves at the elbow. The skin incision is made at the lower border of the axillary hair line between the latissimus dorsi and pectoralis major muscles. Dissection with cautery proceeds down to the flimsy areolar tissue superficial to the chest wall. Gentle blunt dissection is then used in an anterior and cephalad direction. Manual palpation is used to identify the first rib as it approaches the clavicle. A self-retaining retractor is then placed and the Machleder retractor is elevated to facilitate exposure in the axilla. The soft tissue overlying the subclavian vessels and the scalene muscles is swept away with a Kittner blunt dissector. Frequently, a small branch of the subclavian artery must be ligated and divided to fully mobilize the artery. The first rib is identified and the

Figure 1 Machleder retractor used for positioning during transaxillary first rib resection. The patient is placed in a decubitus position with the nonoperative side down. Ample sterile towels are used for padding, and the arm is secured in the retractor with a combination of gauze and elastic wraps.

intercostal muscle attachments are bluntly cleared from the lower edge using a Kittner blunt dissector followed by a flat periosteal elevator [see Figure 2]. The first rib is separated from the underlying pleura by gently sliding a small periosteal elevator beneath the first rib. The pleura is pushed away from the rib, and this mobilization extends from behind the brachial plexus posteriorly to in front of the subclavian vein anteriorly. The subclavius muscle, which has a crescent-shaped ligamentous attachment on the first rib adjacent to the subclavian vein, is sharply divided with scissors, taking care not to injure the subclavian vein. Division of the subclavius muscle provides greater anterior mobilization of the first rib, allowing for more anterior resection, which is of particular importance in venous TOS. The scalene medius fibers are dissected bluntly using a periosteal elevator. Sharp dissection

Figure 2 Gentle dissection of the first rib with a periosteal elevator.

is avoided because of the adjacent course of the long thoracic nerve. The anterior scalene muscle must be clearly visualized between the subclavian artery and vein. A right-angle clamp is then placed behind the anterior scalene muscle, lifting it away from the adjacent artery. The muscle is divided sharply with scissors, leaving as much length as possible attached to the rib [see Figure 3]. This maneuver is performed with care and may need to be repeated multiple times to divide the muscle safely. A bone cutter is then placed anteriorly and the first rib is divided adjacent to the subclavian vein. The posterior division of the rib occurs once the remainder of the rib is mobilized. This allows for optimal visualization of the brachial plexus to prevent injury when cutting the rib posteriorly. The rib cutter is gently applied to the rib just anterior to the brachial plexus. The nerve must be visualized prior to making any cut [see Figure 4]. The rib is divided and removed. The rib is always cut in front of the nerve so that posterior nerve roots are not unintentionally damaged. The remainder of the rib anteriorly and posteriorly is trimmed with a rongeur. The nerve root is pushed away and protected with a Roos retractor as the posterior remnant of the rib is rongeuired. The bone edges should be fairly uniform, and there should be no impingement on the neurovascular structures [see Figure 5]. Saline is then instilled into the axillary cavity, and the patient is given several positive pressure ventilations to check for tears in the parietal pleura. If a pneumothorax is present, a 12 French chest tube is placed in the second intercostal space through a separate stab incision. This is applied to 20 cm of water suction after the arm is lowered and the wound is closed in two layers.

Outcomes

The most common complication of transaxillary thoracic outlet decompression is pneumothorax, occurring in approximately 10% of patients. Fortunately, this is easily dealt with intraoperatively by placement of a small chest tube, which is

Figure 3 Anterior scalene muscle isolated by a right-angle clamp prior to dissection.

Figure 4 Bone cutter used to remove the first rib.

Figure 5 Anatomic space immediately prior to closure. The neurovascular structures are no longer restricted following rib resection.

removed the following day. More serious complications of major vascular or brachial plexus injuries are much less common, occurring in less than 1%. Recurrence of symptoms occurs in up to 10%, and reoperation for recurrent TOS provides other challenges outside the scope of this chapter. There are few objective criteria for measuring success in thoracic outlet decompression. Obviously, the patient's ability to return to normal daily activities, including work, is a good indication of successful therapy. At Johns Hopkins, a prospective study of over 100 patients undergoing thoracic outlet decompression showed statistically significant improvement in quality of life. This was evaluated through the use of

a novel survey instrument.²⁵ The majority of patients in this study were able to return to work or activity within 6 months. Ultimately, successful outcomes depend on thorough diagnostic evaluation, carefully selected and often multimodal therapy, and long-term follow-up.

1 ACUTE ABDOMINAL PAIN

Alex Nagle, MD, FACS

Acute abdominal pain generally refers to previously undiagnosed pain that arises suddenly and is of less than 48 hours' duration.¹ It may be caused by a great variety of intraperitoneal disorders, many of which call for surgical treatment, as well as by a range of extraperitoneal disorders,² which typically do not call for surgical treatment [*see Clinical Evaluation, Tentative Differential Diagnosis, below*]. Abdominal pain that persists for 6 hours or longer is usually caused by disorders of surgical significance.³ The primary goals in the management of patients with acute abdominal pain are (1) to establish a differential diagnosis and a plan for confirming the diagnosis through appropriate imaging studies, (2) to determine whether operative intervention is necessary, and (3) to prepare the patient for operation in a manner that minimizes perioperative morbidity and mortality.

In many cases, these goals are easily accomplished. On occasion, however, the evaluation of patients with acute abdominal pain can be one of the most difficult challenges in clinical surgery. It is essential to keep in mind that most (at least two thirds) of the patients who present with acute abdominal pain have disorders for which surgical intervention is not required.^{2,4,5} In addition, most clinicians depend on recognition of specific patterns and sequences of symptoms and signs to determine the need for further testing and to make decisions regarding the timing of operation; however, at least one third of patients with acute abdominal pain exhibit atypical features that render pattern recognition unreliable.^{2,5} Finally, it is not clear that individual clinicians always or even usually agree on presenting symptoms and physical signs. In one study of abdominal pain in children, agreement between individual observers was reached 50% of the time for the physical sign of rebound tenderness; however, for five other signs (abdominal distention, abdominal tenderness to percussion, abdominal tenderness to palpation, abdominal guarding, and bowel sounds), interobserver agreement was not reached in more than one third of patients. These findings highlight the difficulties inherent in evaluation and management of acute abdominal pain. In addition, they emphasize the importance of integrating care among different providers to minimize loss of information and maximize continuity of care.

Clinical Evaluation

HISTORY

A careful and methodical clinical history should be obtained. Key features of the history include the dimensions of pain (i.e., mode of onset, duration, frequency, character, location,

chronology, radiation, and intensity), as well as the presence or absence of any aggravating or alleviating factors and associated symptoms. Often such a history is more valuable than any single laboratory or x-ray finding and determines the course of subsequent evaluation and management.

Unfortunately, when the ability of clinicians to take an organized and accurate history has been studied, the results have been disappointing.⁶ For this reason, the use of standardized history and physical forms, with or without the aid of diagnostic computer programs, has been recommended.⁷⁻¹⁰ A large-scale study that included 16,737 patients with acute abdominal pain demonstrated that integration of computer-aided diagnosis into management yielded a 20% improvement in diagnostic accuracy.⁷ The study also documented statistically significant reductions in inappropriate admissions, negative laparotomies, serious management errors (e.g., failure to operate on patients who require surgery), and length of hospital stay, as well as statistically significant increases in the number of patients who were immediately discharged home without adverse effects and the promptness with which those requiring surgery underwent operation. Although many factors may have contributed to the observed benefits of computer-aided decision making, it is clear that the use of structured and standardized means of collecting clinical and laboratory data was crucial. An example of such a structured data sheet is the pain chart developed by the World Organization of Gastroenterology (OMGE) [*see Figure 1*]. Because this pain chart is not exhaustive and does not cover all potential situations, individual surgeons may want to add to it; however, they would be well advised not to omit any of the symptoms and signs on the OMGE data sheet from their routine examination of patients with acute abdominal pain.¹¹

The patient's own words often provide important clues to the correct diagnosis. The examiner should refrain from suggesting specific symptoms, except as a last resort. Any questions that must be asked should be open-ended—for example, "What happens when you eat?" rather than "Does eating make the pain worse?" Leading questions should be avoided. When a leading question must be asked, it should be posed first as a negative question (i.e., one that calls for an answer in the negative) because a negative answer to a question is more likely to be honest and accurate. For example, if peritoneal inflammation is suspected, the question asked should be "Does coughing make the pain better?" rather than "Does coughing make the pain worse?"

The mode of onset of abdominal pain may help the examiner determine the severity of the underlying disease. Pain that has a sudden onset suggests an intra-abdominal catastrophe, such as a ruptured abdominal aortic aneurysm (AAA), a

perforated viscus, or a ruptured ectopic pregnancy; a near loss of consciousness or stamina associated with sudden-onset pain should heighten the level of concern for such a catastrophe. Rapidly progressive pain that becomes intensely focused in a well-defined area within a period of a few minutes to an hour or two suggests a condition such as acute cholecystitis or pancreatitis. Pain that has a gradual onset over several hours, usually beginning as slight or vague discomfort and slowly progressing to steady and more localized pain, suggests a subacute process and is characteristic of processes that lead to peritoneal inflammation. Numerous disorders may be associated with this mode of onset, including acute appendicitis, diverticulitis, pelvic inflammatory disease (PID), and intestinal obstruction.

Pain can be either intermittent or continuous. Intermittent or cramping pain (colic) is pain that occurs for a short period (a few minutes), followed by longer periods (a few minutes to one half-hour) of complete remission during which there is no pain at all. Intermittent pain is characteristic of obstruction of a hollow viscus and results from vigorous peristalsis in the wall of the viscus proximal to the site of obstruction. This pain is perceived as deep in the abdomen and is poorly localized. The patient is restless, may writhe about incessantly in an effort to find a comfortable position, and often presses on the abdominal wall in an attempt to alleviate the pain. Whereas the intermittent pain associated with intestinal obstruction (typically described as gripping and mounting) is usually severe but bearable, the pain associated with obstruction of small conduits (e.g., the biliary tract, the ureters, and the uterine tubes) often becomes unbearable. Obstruction of the gallbladder or the bile ducts gives rise to a type of pain often referred to as biliary colic; however, this term is a misnomer in that biliary pain is usually constant because of the lack of a strong muscular coat in the biliary tree and the absence of regular peristalsis.

Continuous or constant pain is pain that is present for hours or days without any period of complete relief; it is more common than intermittent pain. Continuous pain is usually indicative of a process that will lead, or has already led, to peritoneal inflammation or ischemia. It may be of steady intensity throughout, or it may be associated with intermittent pain. For example, the typical colicky pain associated with simple intestinal obstruction changes when strangulation occurs, becoming continuous pain that persists between episodes or waves of cramping pain.

Certain types of pain are generally held to be typical of certain pathologic states. For example, the pain of a perforated ulcer is often described as burning, that of a dissecting aneurysm as tearing, and that of bowel obstruction as gripping. One may imagine that the first type of pain is explained by the efflux of acid, the second by the sudden expansion of the retroperitoneum, and the third by the churning of hyperperistalsis. Colorful as these images may be, in most cases, the pain begins in a nondescript way. It is only by carefully following the patient's description of the evolution and time course of the pain that such images may be formed with confidence.

For several reasons—atypical pain patterns, dual innervation by visceral and somatic afferents, normal variations in organ position, and widely diverse underlying pathologic states—the

location of abdominal pain is only a rough guide to diagnosis. It is nevertheless true that in most disorders, the pain tends to occur in characteristic locations, such as the right upper quadrant (cholecystitis), the right lower quadrant (appendicitis), the epigastrium (pancreatitis), or the left lower quadrant (sigmoid diverticulitis) [see Figure 2]. It is important to determine the location of the pain at onset because this may differ from the location at the time of presentation (so-called shifting pain). In fact, the chronological sequence of events in the patient's history is often more important for diagnosis than the location of the pain alone. For example, the classic pain of appendicitis begins in the periumbilical region and settles in the right lower quadrant. Another example is the pain from a perforated ulcer which can shift to the right lower quadrant as escaping gastroduodenal content tracks down the right gutter.

It is also important to take into account radiation or referral of the pain, which tends to occur in characteristic patterns [see Figure 3]. For example, biliary pain is referred to the right subscapular area, and the boring pain of pancreatitis typically radiates straight through to the back. Obstruction of the small intestine and the proximal colon is referred to the umbilicus, and obstruction distal to the splenic flexure is often referred to the suprapubic area. Spasm in the ureter often radiates to the suprapubic area and into the groin. The more severe the pain is, the more likely it is to be associated with referral to other areas.

The intensity or severity of the pain is related to the magnitude of the underlying insult. It is important to distinguish between the intensity of the pain and the patient's reaction to it because there appear to be significant individual differences with respect to tolerance of and reaction to pain. Pain that is intense enough to awaken the patient from sleep usually indicates a significant underlying organic cause. Past episodes of pain and factors that aggravate or relieve the pain often provide useful diagnostic clues. For example, pain caused by peritonitis tends to be exacerbated by motion, deep breathing, coughing, or sneezing, and patients with peritonitis tend to lie quietly in bed and avoid any movement. The typical pain of acute pancreatitis is exacerbated by lying down and relieved by sitting up. Pain that is relieved by eating or taking antacids suggests duodenal ulcer disease, whereas diffuse abdominal pain that appears 30 minutes to 1 hour after meals suggests intestinal angina.

Associated gastrointestinal symptoms (e.g., nausea, vomiting, anorexia, diarrhea, and constipation) often accompany abdominal pain; however, these symptoms are nonspecific and therefore may not be of great value in the differential diagnosis. Vomiting in particular is common: when sufficiently stimulated by pain impulses traveling via secondary visceral afferent fibers, the medullary vomiting centers activate efferent fibers and cause reflex vomiting. Once again, the chronology of events is important in that pain often precedes vomiting in patients with conditions necessitating operation, whereas the opposite is usually the case in patients with medical (i.e., nonsurgical) conditions.^{5,12} This is particularly true for adult patients with acute appendicitis, in whom pain almost always precedes vomiting by several hours. In children, vomiting is commonly observed closer to the onset of the pain, although it is rarely the initial symptom.

Figure 2 In most disorders that give rise to acute abdominal pain, the pain tends to occur in specific locations. (a) Diffuse pain suggests a certain set of diagnostic possibilities. (b) Differing groups of disorders give rise to abdominal pain in the epigastric, umbilical, and hypogastric regions. (c) Disorders that give rise to acute abdominal pain may be grouped according to the quadrant of the abdomen in which pain tends to occur.

Figure 3 Pain of abdominal origin tends to be referred in characteristic patterns.⁸⁰ The more severe the pain is, the more likely it is to be referred. Shown are anterior (*left*) and posterior (*right*) areas of referred pain.

Similarly, constipation may result from a reflex paralytic ileus when sufficiently stimulated visceral afferent fibers activate efferent sympathetic fibers (splanchnic nerves) to reduce intestinal peristalsis. Diarrhea is characteristic of gastroenteritis but may also accompany incomplete intestinal or colonic obstruction. More significant is a history of obstipation because if it can be definitely established that a patient with acute abdominal pain has not passed gas or stool for 24 to 48 hours, it is certain that some degree of intestinal obstruction is present. Other associated symptoms that should be noted include jaundice, melena, hematochezia, hematemesis, and hematuria. These symptoms are much more specific than the ones just discussed and can be extremely valuable in the differential diagnosis. Most conditions that cause acute abdominal pain of surgical significance are associated with some degree of fever if they are allowed to continue long enough. Fever suggests an inflammatory process; however, it is usually low grade and often absent altogether, particularly in elderly and immunocompromised patients. The combination of a high fever with chills and rigors indicates bacteremia, and concomitant changes in mental status (e.g., agitation, disorientation, and lethargy) suggest impending septic shock.

A history of trauma (even if the patient considers the traumatic event trivial) should be actively sought in all cases of unexplained acute abdominal pain; such a history may not be readily volunteered (as is often the case with trauma resulting from domestic violence). The history may be particularly relevant in a patient taking anticoagulants and presenting with acute onset of abdominal pain accompanied by tenderness but no clear signs of inflammation. Hematoma within the rectus muscle sheath can easily be mistaken for appendicitis or other lower abdominal illnesses; hematoma

elsewhere can produce symptoms of obstruction or acute bleeding into the peritoneum and the retroperitoneum. In female patients, it is essential to obtain a detailed gynecologic history that includes the timing of symptoms within the menstrual cycle, the date of the last menses, previous and current use of contraception, any abnormal vaginal bleeding or discharge, an obstetric history, and any risk factors for ectopic pregnancy (e.g., PID, use of an intrauterine device, or previous ectopic or tubal surgery). Pregnancy should be excluded in all women of childbearing age with abdominal pain.

A complete history of previous medical conditions must be obtained because associated diseases of the cardiac, pulmonary, and renal systems may give rise to acute abdominal symptoms and may also significantly affect the morbidity and mortality associated with surgical intervention. The use of regular and as needed medications must also be obtained. Weight changes, past illnesses, recent travel, and environmental exposure to toxins or infectious agents used should also be investigated. A history of previous abdominal operations should be obtained but should not be relied on too heavily in the absence of operative reports. A careful family history is important for detection of hereditary disorders that may cause acute abdominal pain. A detailed social history should also be obtained that includes any history of tobacco, alcohol, or illicit drug use, as well as a sexual history.

TENTATIVE DIFFERENTIAL DIAGNOSIS

Once the history has been obtained, the examiner should generate a tentative differential diagnosis and carry out the physical examination in search of specific signs or findings that either rule out or confirm the diagnostic possibilities.

Given the diversity of conditions that can cause acute abdominal pain [see Table 1 and Table 2], there is no substitute for general awareness of the most common causes of acute abdominal pain and the influence of age, gender, and geography on the likelihood of any of these potential causes. Although acute abdominal pain is the most common surgical emergency and most non-trauma-related surgical admissions (and

1% of all hospital admissions) are accounted for by patients complaining of abdominal pain, little information is available regarding the clinical spectrum of disease in these patients.¹³ Nevertheless, detailed epidemiologic information can be an invaluable asset in the diagnosis and treatment of acute abdominal pain. Now that patients from different parts of the world are increasingly being seen in North American

Table 1 Intraperitoneal Causes of Acute Abdominal Pain

Inflammatory	Mechanical (obstruction, acute distention)
Peritoneal	Hollow visceral
Chemical and nonbacterial peritonitis	Intestinal obstruction
Perforated peptic ulcer/biliary tree, pancreatitis, ruptured ovarian cyst, mittelschmerz	Adhesions, hernias, neoplasms, volvulus
Bacterial peritonitis	Intussusception, gallstone ileus, foreign bodies
Primary peritonitis	Bezoars, parasites
Pneumococcal, streptococcal, tuberculous	Biliary obstruction
Spontaneous bacterial peritonitis	Calculi, neoplasms, choledochal cyst, hemobilia
Perforated hollow viscus	Solid visceral
Esophagus, stomach, duodenum, small intestine, bile duct, gallbladder, colon, urinary bladder	Acute splenomegaly
Hollow visceral	Acute hepatomegaly (congestive heart failure, Budd-Chiari syndrome)
Appendicitis	Mesenteric
Cholecystitis	Omental torsion
Peptic ulcer	Pelvic
Gastroenteritis	Ovarian cyst
Gastritis	Torsion or degeneration of fibroid
Duodenitis	Ectopic pregnancy
Inflammatory bowel disease	Hemoperitoneum
Meckel diverticulitis	Ruptured hepatic neoplasm
Colitis (bacterial, amebic)	Spontaneous splenic rupture
Diverticulitis	Ruptured mesentery
Solid visceral	Ruptured uterus
Pancreatitis	Ruptured graafian follicle
Hepatitis	Ruptured ectopic pregnancy
Pancreatic abscess	Ruptured aortic or visceral aneurysm
Hepatic abscess	Ischemic
Splenic abscess	Mesenteric thrombosis
Mesenteric	Hepatic infarction (toxemia, purpura)
Lymphadenitis (bacterial, viral)	Splenic infarction
Epiploic appendagitis	Omental ischemia
Pelvic	Strangulated hernia
Pelvic inflammatory disease (salpingitis)	Neoplastic
Tubo-ovarian abscess	Primary or metastatic intraperitoneal neoplasms
Endometritis	Traumatic
	Blunt trauma
	Penetrating trauma
	Iatrogenic trauma
	Domestic violence
	Miscellaneous
	Endometriosis

Adapted from McFadden DW et al.⁸¹

Table 2 Extraperitoneal Causes of Acute Abdominal Pain

Genitourinary	Neurogenic
Pyelonephritis	Herpes zoster
Perinephric abscess	Tabes dorsalis
Renal infarct	Nerve root compression
Nephrolithiasis	Spinal cord tumors
Ureteral obstruction (lithiasis, tumor)	Osteomyelitis of the spine
Acute cystitis	Abdominal epilepsy
Prostatitis	Abdominal migraine
Seminal vesiculitis	Multiple sclerosis
Epididymitis	Inflammatory
Orchitis	Schönlein-Henoch purpura
Testicular torsion	Systemic lupus erythematosus
Dysmenorrhea	Polyarteritis nodosa
Threatened abortion	Dermatomyositis
Pulmonary	Scleroderma
Pneumonia	Infectious
Empyema	Bacterial
Pulmonary embolus	Parasitic (malaria)
Pulmonary infarction	Viral (measles, mumps, infectious mononucleosis)
Pneumothorax	Rickettsial (Rocky Mountain spotted fever)
Cardiac	Hematologic
Myocardial ischemia	Sickle cell crisis
Myocardial infarction	Acute leukemia
Acute rheumatic fever	Acute hemolytic states
Acute pericarditis	Coagulopathies
Metabolic	Pernicious anemia
Acute intermittent porphyria	Other dyscrasias
Familial Mediterranean fever	Vascular
Hypolipoproteinemia	Vasculitis
Hemochromatosis	Periarteritis
Hereditary angioneurotic edema	Toxins
Endocrine	Bacterial toxins (tetanus, <i>Staphylococcus</i>)
Diabetic ketoacidosis	Insect venom (black widow spider)
Hyperparathyroidism (hypercalcemia)	Animal venom
Acute adrenal insufficiency (Addisonian crisis)	Heavy metals (lead, arsenic, mercury)
Hyperthyroidism or hypothyroidism	Poisonous mushrooms
Musculoskeletal	Drugs
Rectus sheath hematoma	Withdrawal from narcotics
Arthritis/diskitis of thoracolumbar spine	Retroperitoneal
Psychogenic	Retroperitoneal hemorrhage (spontaneous adrenal hemorrhage)
Hypochondriasis	Psoas abscess
Somatization disorders	
Factitious	
Munchausen syndrome	
Malingering	

emergency rooms, it is important to consider endemic diseases, including tuberculosis,^{14,15} parasitic diseases,^{16–18} bezoars from unusual dietary habits,^{19,20} and unusual malignancies.^{21,22}

The value of detailed epidemiologic knowledge notwithstanding, it is worthwhile to keep in mind the truism that common things are common. Regarding which things are common, the most extensive information currently available comes from the ongoing survey begun in 1977 by the Research Committee of the OMGE. As of the last progress report on this survey, which was published in 1988, more than 200 physicians at 26 centers in 17 countries had accumulated data on 10,320 patients with acute abdominal pain [see Table 3].²³ The most common diagnosis in these patients was nonspecific abdominal pain (NSAP)—that is, the retrospective diagnosis of exclusion in which no cause for the pain can be identified.^{24,25} NSAP accounted for 34% of all patients seen; the four most common diagnoses accounted for more than 75%. The most common surgical diagnosis in the OMGE survey was acute appendicitis, followed by acute cholecystitis, small bowel obstruction, and gynecologic disorders. Relatively few patients had perforated peptic ulcer, a finding that confirms the current downward trend in the incidence of this condition. Cancer was found to be a significant cause of acute abdominal pain. There was little variation in the geographic distribution of surgical causes of acute abdominal pain (i.e., conditions necessitating operation) among

developed countries. In patients who required surgery, the most common causes were acute appendicitis (42.6%), acute cholecystitis (14.7%), small bowel obstruction (6.2%), perforated peptic ulcer (3.7%), and acute pancreatitis (4.5%).²³ The OMGE survey's finding that NSAP was the most common diagnosis in patients with acute abdominal pain has been confirmed by several studies^{12,13,25}; the finding that acute appendicitis, cholecystitis, and intestinal obstruction were the three most common diagnoses in patients with acute abdominal pain who require operation has also been amply confirmed [see Table 3].^{1,12,13}

The data described so far provide a comprehensive picture of the most likely diagnoses for patients with acute abdominal pain in many centers around the world; however, this picture does not take into account the effect of age on the relative likelihood of the various potential diagnoses. It is well known that the disease spectrum of acute abdominal pain is different in different age groups, especially in the very old^{4,26,27} and the very young.^{28–30} In the OMGE survey, well over 90% of cases of acute abdominal pain in children were diagnosed as having acute appendicitis (32%) or NSAP (62%).²⁸ Similar age-related differences in the spectrum of disease have been confirmed by other studies,¹⁶ as have various gender-related differences.

This variation in the disease spectrum is readily apparent when the 10,320 patients from the OMGE survey are segregated by age [see Table 4]. In patients 50 years of age

Table 3 Frequency of Specific Diagnoses in Patients with Acute Abdominal Pain

Diagnosis	Frequency in Individual Studies (% of Patients)					
	OMGE ²³ (N = 10,320)	Wilson et al ⁸² (N = 1,196)	Irvin ¹³ (N = 1,190)	Brewer et al ¹² (N = 1,000)	de Dombal ¹ (N = 552)	Hawthorn ⁸³ (N = 496)
Nonspecific abdominal pain	34.0	45.6	34.9	41.3	50.5	36.0
Acute appendicitis	28.1	15.6	16.8	4.3	26.3	14.9
Acute cholecystitis	9.7	5.8	5.1	2.5	7.6	5.9
Small bowel obstruction	4.1	2.6	14.8	2.5	3.6	8.6

Table 4 Frequency of Specific Diagnoses in Younger and Older Patients with Acute Abdominal Pain in the OMGE Study

Diagnosis	Frequency (% of Patients)	
	Age < 50 yr (N = 6,317)	Age ≥ 50 yr (N = 2,406)
Nonspecific abdominal pain	39.5	15.7
Appendicitis	32.0	15.2
Cholecystitis	6.3	20.9
Obstruction	2.5	12.3
Pancreatitis	1.6	7.3
Diverticular disease	< 0.1	5.5
Cancer	< 0.1	4.1
Hernia	< 0.1	3.1
Vascular disease	< 0.1	2.3

OMGE = World Organization of Gastroenterology.
Adapted from de Dombal FT et al.²³ and Telfer S et al.²⁷

or older,²⁷ cholecystitis was more common than either NSAP or acute appendicitis; small bowel obstruction, diverticular disease, and pancreatitis were all approximately five times more common than in patients younger than 50 years. Hernias were also a much more common problem in older patients. In the entire group of patients, only 1 in every 10 instances of intestinal obstruction was attributable to a hernia, whereas in patients 50 years of age or older, 1 in every 3 instances was caused by an undiagnosed hernia. Cancer was 40 times more likely to be the cause of acute abdominal pain in patients 50 years of age or older; vascular diseases (including myocardial infarction, mesenteric ischemia, and ruptured AAA) were 25 times more common in patients 50 years of age or older and 100 times more common in patients older than 70 years. What is more, outcome was clearly related to age: mortality was significantly higher in patients older than 70 years (5%) than in those younger than 50 years (< 1%). Whereas the peak incidence of acute abdominal pain occurred in patients in their teens and twenties,²⁸ the great majority of deaths occurred in patients older than 70 years.²⁷

PHYSICAL EXAMINATION

In the physical examination of a patient, as in the taking of the history, there is no substitute for organization and patience; the amount of information that can be obtained is directly proportional to the gentleness and thoroughness of the examiner. The physical examination begins with a brief but thorough evaluation of the patient's general appearance and ability to answer questions. The degree of obvious pain should be estimated. The patient's position in bed should be noted. A patient who lies motionless with flexed hips and knees is more likely to have generalized peritonitis. A restless patient who writhes about in bed is more likely to have colicky pain.

The area of maximal pain should be identified before the physical examination is begun. The examiner can easily do this by simply asking the patient to cough and then to point

with two fingers to the area where pain seems to be focused. This allows the examiner to avoid the area in the early stages of the examination and to confirm it at a later stage without causing the patient unnecessary discomfort in the meantime.

The physical examination should be directed, in the sense that it should address critical findings that would confirm or exclude the likeliest disorders in the differential diagnosis. In this context, however, it should be complete. Some processes that can cause abdominal pain occur within the chest (e.g., pneumonia, ischemic heart disease or arrhythmia, esophageal muscular disorders); thus, auscultation of the lungs and the heart is integral to the examination. A pelvic examination should be performed in women, and an examination of the rectum and the groin should be performed in all patients. It should not be assumed that advanced imaging technology (e.g., computed tomography [CT], magnetic resonance imaging [MRI], or ultrasonography [US]) will provide the diagnosis most quickly or with the highest level of confidence. The sensitivity and specificity (not to mention the cost-effectiveness) of any laboratory or imaging study are grounded in the intelligent gathering and categorization of signs and symptoms.^{31,32}

Before attention is directed to the patient's abdomen, signs of systemic illness should be sought. Systemic signs of shock (e.g., diaphoresis, pallor, hypothermia, tachypnea, tachycardia with orthostasis, and frank hypotension) usually accompany a rapidly progressive or advanced intra-abdominal condition and, in the absence of extra-abdominal causes, are indications for immediate laparotomy. The absence of any alteration in vital signs, however, does not necessarily exclude a serious intra-abdominal process.

Examination of the abdomen begins with the patient resting in a comfortable supine position. A right-handed examiner should stand on the patient's right side, and the patient's abdomen should be level with the elbow at rest. In some cases, to make sure that the examination is unhurried and the patient's anxiety is allayed, the examiner may find it useful to sit at the bedside. The examination should include inspection, auscultation, percussion, and palpation of all areas of the abdomen, the flanks, and the groin (including all hernia orifices) in addition to rectal and genital examinations (and, in female patients, a full gynecologic examination). A systematic approach is crucial: an examiner who methodically follows a set pattern of abdominal examination every time will be rewarded more frequently than one who improvises haphazardly with each patient.

The first step in the abdominal examination is careful inspection of the anterior and posterior abdominal walls, the flanks, the perineum, and the genitalia for previous surgical scars (possible adhesions), hernias (incarceration or strangulation), distention (intestinal obstruction), obvious masses (distended gallbladder, abscesses, or tumors), ecchymosis or abrasions (trauma), striae (pregnancy or ascites), an everted umbilicus (increased intra-abdominal pressure), visible pulsations (aneurysm), visible peristalsis (obstruction), limitation of movement of the abdominal wall with ventilatory movements (peritonitis), or engorged veins (portal hypertension).

The next recommended step in the abdominal examination is auscultation. Although it is important to note the presence (or absence) of bowel sounds and their quality, auscultation

is probably the least rewarding aspect of the physical examination. Severe intra-abdominal conditions, even intra-abdominal catastrophes, may occur in patients with normal bowel sounds, and patients with silent abdomens may have no significant intra-abdominal pathology at all. In general, however, the absence of bowel sounds indicates a paralytic ileus; hyperactive or hypoactive bowel sounds often are variations of normal activity; and high-pitched bowel sounds with splashes, tinkles (echoing as in a large cavern), or rushes (prolonged, loud gurgles) indicate mechanical bowel obstruction.

The third step is percussion to search for any areas of dullness, fluid collections, sections of gas-filled bowel, or pockets of free air under the abdominal wall. Tympany may be present in patients with bowel obstruction or hollow viscus perforation. Percussion can be useful as a way of estimating organ size and of determining the presence of ascites (signaled by a fluid wave or shifting dullness). Gentle percussion over the four quadrants of the abdomen can also be used to elicit a sign of peritoneal irritation, and patients tolerate this maneuver reasonably well. Pain associated with mild levels of percussion is a good indicator of peritonitis if the maneuver is performed in the same way each time. In general, however, maneuvers associated with palpation are best for determining whether peritonitis is present.

The last step, palpation, is the most informative aspect of the physical examination. Palpation of the abdomen must be done very gently to avoid causing additional pain early in the examination. It should begin as far as possible from the area of maximal pain and then should gradually advance toward this area, which should be the last to be palpated. The examiner should place the entire hand on the patient's abdomen with the fingers together and extended, applying pressure with the pulps (not the tips) of the fingers by flexing the wrists and

the metacarpophalangeal joints. It is essential to determine whether true involuntary muscle guarding (muscle spasm) is present. This determination is made by means of gentle palpation over the abdominal wall while the patient takes a long, deep breath. If guarding is voluntary, the underlying muscle immediately relaxes under the gentle pressure of the palpating hand. If, however, the patient has true involuntary guarding, the muscle remains in spasm (i.e., taut and rigid) throughout the respiratory cycle (so-called boardlike abdomen). True involuntary guarding is indicative of localized or generalized peritonitis. It must be remembered that muscle rigidity is relative: for example, muscle guarding may be less pronounced or absent in debilitated and elderly patients who have poor abdominal musculature. In addition, the evaluation of muscle guarding is dependent on the patient's cooperation.

Palpation is also useful for determining the extent and severity of the patient's tenderness. Diffuse tenderness indicates generalized peritoneal inflammation. Mild diffuse tenderness without guarding usually indicates gastroenteritis or some other inflammatory intestinal process without peritoneal inflammation. Localized tenderness suggests an early stage of disease with limited peritoneal inflammation. Rebound tenderness is elicited by applying gentle but deep pressure to the region of interest and then letting go abruptly. As a means of distraction, the examiner may use the stethoscope to apply the pressure. The main difficulties associated with palpation are that the deep pressure may increase anxiety and that the surprise of the sudden withdrawal may elicit pain where peritoneal irritation is not the cause.

Careful palpation can elicit several specific signs [see Table 5], such as the Rovsing sign (pain in the right lower quadrant when the left lower quadrant is palpated deeply), which is associated with acute appendicitis, and the Murphy sign (arrest of inspiration when the right upper quadrant is

Table 5 Common Abdominal Signs and Findings Noted on Physical Examination

Sign or Finding	Description	Associated Clinical Condition(s)
Aaron sign	Referred pain or feeling of distress in epigastrium or precordial region on continued firm pressure over the McBurney point	Acute appendicitis
Ballance sign	Presence of dull percussion note in both flanks, constant on left side but shifting with change of position on right side	Ruptured spleen
Bassler sign	Sharp pain elicited by pinching appendix between thumb of examiner and iliacus muscle	Chronic appendicitis
Beevor sign	Upward movement of umbilicus	Paralysis of lower portions of rectus abdominis muscles
Blumberg sign	Transient abdominal wall rebound tenderness	Peritoneal inflammation
Carnett sign	Disappearance of abdominal tenderness when anterior abdominal muscles are contracted	Abdominal pain of intra-abdominal origin
Chandelier sign	Intense lower abdominal and pelvic pain on manipulation of cervix	Pelvic inflammatory disease
Charcot sign	Intermittent right upper quadrant abdominal pain, jaundice, and fever	Choledocholithiasis
Chaussier sign	Severe epigastric pain in gravid female	Prodrome of eclampsia
Claybrook sign	Transmission of breath and heart sounds through abdominal wall	Ruptured abdominal viscus
Courvoisier sign	Palpable, nontender gallbladder in presence of clinical jaundice	Periampullary neoplasm
Cruveilhier sign	Varicose veins radiating from umbilicus (caput medusae)	Portal hypertension

Table 5 (continued) Common Abdominal Signs and Findings Noted on Physical Examination

Sign or Finding	Description	Associated Clinical Condition(s)
Cullen sign	Periumbilical darkening of skin from blood	Hemoperitoneum (especially in ruptured ectopic pregnancy)
Cutaneous hyperesthesia	Increased abdominal wall sensation to light touch	Parietal peritoneal inflammation secondary to inflammatory intra-abdominal pathology
Dance sign	Slight retraction in area of right iliac fossa	Intussusception
Danforth sign	Shoulder pain on inspiration	Hemoperitoneum (especially in ruptured ectopic pregnancy)
Direct abdominal wall tenderness	—	Localized inflammation of abdominal wall, peritoneum, or an intra-abdominal viscus
Fothergill sign	Abdominal wall mass that does not cross midline and remains palpable when rectus muscle is tense	Rectus muscle hematoma
Grey Turner sign	Local areas of discoloration around umbilicus and flanks	Acute hemorrhagic pancreatitis
Iliopsoas sign	Elevation and extension of leg against pressure of examiner's hand causes pain	Appendicitis (retrocecal) or an inflammatory mass in contact with psoas
Kehr sign	Left shoulder pain when patient is supine or in the Trendelenburg position (pain may occur spontaneously or after application of pressure to left subcostal region)	Hemoperitoneum (especially ruptured spleen)
Kustner sign	Palpable mass anterior to uterus	Dermoid cyst of ovary
Mannkopf sign	Acceleration of pulse when a painful point is pressed on by examiner	Absent in factitious abdominal pain
McClintock sign	Heart rate > 100 beats/min 1 hr postpartum	Postpartum hemorrhage
Murphy sign	Palpation of right upper abdominal quadrant during deep inspiration results in inspiratory arrest	Acute cholecystitis
Obturator sign	Flexion of right thigh at right angles to trunk and external rotation of same leg in supine position result in hypogastric pain	Appendicitis (pelvic appendix); pelvic abscess; an inflammatory mass in contact with muscle
Puddle sign	Alteration in intensity of transmitted sound in intra-abdominal cavity secondary to percussion when patient is positioned on all fours and stethoscope is gradually moved toward flank opposite percussion	Free peritoneal fluid
Ransohoff sign	Yellow pigmentation in umbilical region	Ruptured common bile duct
Rovsing sign	Pain referred to the McBurney point on application of pressure to descending colon	Acute appendicitis
Subcutaneous crepitation	Palpable crepitus in abdominal wall	Subcutaneous emphysema or gas gangrene
Summer sign	Increased abdominal muscle tone on exceedingly gentle palpation of right or left iliac fossa	Early appendicitis; nephrolithiasis; ureterolithiasis; ovarian torsion
Ten Horn sign	Pain caused by gentle traction on right spermatic cord	Acute appendicitis
Toma sign	Right-sided tympany and left-sided dullness in supine position as a result of peritoneal inflammation and subsequent mesenteric contraction of intestine to right side of abdominal cavity	Inflammatory ascites

Adapted from Hickey MS et al.⁶

deeply palpated), which is associated with acute cholecystitis. These signs are indicative of localized peritoneal inflammation. Similarly, specific maneuvers can elicit signs of localized peritoneal irritation. The psoas sign is elicited by placing the patient in the left lateral decubitus position and extending the right leg. In settings where appendicitis is suspected, pain on extension of the right leg indicates that the psoas is irritated and thus that the inflamed appendix is in a retrocecal position. The obturator sign is elicited by raising the flexed right leg and rotating the thigh internally. In settings where appendicitis is suspected, pain on rotation of the right thigh indicates that the obturator is irritated and thus that the inflamed

appendix is in a pelvic position. The Kehr sign is elicited when the patient is placed in the Trendelenburg position. Pain in the shoulder indicates irritation of the diaphragm by a noxious fluid (e.g., gastric contents from a perforated ulcer, pus from a ruptured appendix, or free blood from a fallopian tube pregnancy). Another useful maneuver is the Carnett test, in which the patient elevates his or her head off the bed, thus tensing the abdominal muscles. When the pain is caused by abdominal wall conditions (e.g., rectal sheath hematoma), tenderness to palpation persists, but when the pain is caused by intraperitoneal conditions, tenderness to palpation decreases or disappears (the Carnett sign).

Rectal, genital, and (in women) pelvic examinations are essential to the evaluation of all patients with acute abdominal pain. The rectal examination should include evaluation of sphincter tone, tenderness (localized versus diffuse), and prostate size and tenderness, as well as a search for the presence of hemorrhoids, masses, fecal impaction, foreign bodies, and gross or occult blood. The genital examination should search for adenopathy, masses, discoloration, edema, and crepitus. The pelvic examination in women should check for vaginal discharge or bleeding, cervical discharge or bleeding, cervical mobility and tenderness, uterine tenderness, uterine size, and adnexal tenderness or masses. Although a carefully performed pelvic examination can be invaluable in differentiating nonsurgical conditions (e.g., pelvic inflammatory disease and tubo-ovarian abscess) from conditions necessitating prompt operation (e.g., acute appendicitis), the possibility that a surgical condition is present should not be prematurely dismissed solely on the basis of a finding of tenderness on a pelvic or rectal examination.

Investigative Studies

Laboratory tests and imaging studies rarely, if ever, establish a definitive diagnosis by themselves; however, if used in the correct clinical setting, they can confirm or exclude specific diagnoses suggested by the history and the physical examination.

LABORATORY TESTS

In all patients except those in extremis, a complete blood count, blood chemistries, and a urinalysis are routinely obtained before a decision to operate. The hematocrit is important in that it allows the surgeon to detect significant changes in plasma volume (e.g., dehydration caused by vomiting, diarrhea, or fluid loss into the peritoneum or the intestinal lumen), preexisting anemia, or bleeding. An elevated white blood cell (WBC) count is indicative of an inflammatory process and is a particularly helpful finding if associated with a marked left shift; however, the presence or absence of leukocytosis should never be the single deciding factor as to whether the patient should undergo an operation. A low WBC count may be a feature of viral infections, gastroenteritis, or NSAP. Other tests, such as C-reactive protein assay, may be useful for increasing confidence in the diagnosis of an acute inflammatory condition. An important consideration in the use of any such test is that derangements develop over time, becoming more likely as the illness progresses; thus, serial examinations might be more useful than a single test result obtained at an arbitrary point. Indeed, for the diagnosis of acute appendicitis, serial observations of the leukocyte count and the C-reactive protein level have been shown to possess greater predictive value than single observations.³³

Serum electrolyte, blood urea nitrogen, and creatinine concentrations are useful in determining the nature and extent of fluid losses. Blood glucose and other blood chemistries may also be helpful. Liver function tests (serum bilirubin, alkaline phosphatase, and transaminase levels) are mandatory when abdominal pain is suspected of being hepatobiliary in origin. Similarly, amylase and lipase determinations are mandatory when pancreatitis is suspected, although it must be remembered that amylase levels may be low or normal in patients with pancreatitis and may be markedly elevated in patients

with other conditions (e.g., intestinal obstruction, mesenteric thrombosis, and perforated ulcer).

Urinalysis may reveal red blood cells (RBCs) (suggestive of renal or ureteral calculi), WBCs (suggestive of urinary tract infection or inflammatory processes adjacent to the ureters, such as retrocecal appendicitis), increased specific gravity (suggestive of dehydration), glucose, ketones (suggestive of diabetes), or bilirubin (suggestive of hepatitis). A pregnancy test should be obtained in any woman of childbearing age who is experiencing acute abdominal pain.

Electrocardiography is mandatory in elderly patients and in patients with a history of cardiomyopathy, dysrhythmia, or ischemic heart disease. Abdominal pain may be a manifestation of myocardial disease, and the physiologic stress of acute abdominal pain can increase myocardial oxygen demands and induce ischemia in patients with coronary artery disease.

IMAGING

Until relatively recently, initial radiologic evaluation of the patient with acute abdominal pain included plain films of the abdomen in the supine and standing positions and chest radiographs.³⁴ Currently, CT scanning (when available) is generally considered more likely to be helpful in most situations.^{35,36} Still, some situations remain in which plain films may be a more useful and safe form of investigation—as, for example, when a strangulating obstruction is thought to be the most likely diagnosis and plain films are used for rapid confirmation. If the diagnosis of strangulating obstruction is in doubt, however, CT scanning—particularly with the newer generations of scanning instruments—is useful for making a definitive diagnosis and for identifying clinically unsuspected strangulation.^{37–39}

When performed in the correct clinical setting, imaging studies may confirm diagnoses such as pneumonia (signaled by pulmonary infiltrates); intestinal obstruction (air-fluid levels and dilated loops of bowel); intestinal perforation (pneumoperitoneum); biliary, renal, or ureteral calculi (abnormal calcifications); appendicitis (fecalith); incarcerated hernia (bowel protruding beyond the confines of the peritoneal cavity); mesenteric infarction (air in the portal vein); chronic pancreatitis (pancreatic calcifications); acute pancreatitis (the so-called colon cutoff sign); visceral aneurysms (calcified rim); retroperitoneal hematoma or abscess (obliteration of the psoas shadow); and ischemic colitis (so-called thumbprinting on the colonic wall).

Although in most settings, CT is the preferred modality for primary evaluation of acute abdominal pain, there are certain settings in which US should be considered. When gallstones are considered a likely diagnosis, US is more apt to be diagnostic than CT is, given that about 85% of gallstones are not detectable by x-rays. In disorders of the female genitourinary tract, US is also quite sensitive and specific for diagnoses such as ovarian cyst, fallopian tube pregnancy, and intrauterine pregnancy. Although there are reassuring reports that the risks of radiation from CT scanning can be managed in children and pregnant women with abdominal pain,^{40,41} theoretical concerns remain regarding the teratogenicity of the radiation dose.⁴² Accordingly, it would seem prudent to consider US the preferred initial imaging test for such patients. In these circumstances, CT is employed only if the diagnosis

remains unresolved and if the potential delay in diagnosis (from not obtaining a CT scan) is likely to cause harm.

Working or Presumed Diagnosis

The tentative differential diagnosis developed on the basis of the clinical history is refined on the basis of the physical examination and the investigative studies performed, and a working or presumed diagnosis is generated. Once a working diagnosis has been established, subsequent management depends on the accepted treatment for the particular condition believed to be present. In general, the course of management follows four basic pathways [see Management: Surgical versus Nonsurgical Treatment, *below*], depending on whether the patient (1) has an acute surgical condition that necessitates immediate laparotomy, (2) is believed to have an underlying surgical condition that does not necessitate immediate laparotomy but does call for urgent or early operation, (3) has an uncertain diagnosis that does not necessitate immediate or urgent laparotomy and that may prove to be nonsurgical, or (4) is believed to have an underlying nonsurgical condition.

It must be emphasized that the patient must be constantly reevaluated (preferably by the same examiner) even after the working diagnosis has been established. If the patient does not respond to treatment as expected, the working diagnosis must be reconsidered, and the possibility that another condition exists must be immediately entertained and investigated by returning to the differential diagnosis.

Management: Surgical versus Nonsurgical Treatment

ACUTE SURGICAL ABDOMEN

A thorough but expeditious approach to patients with acute abdominal pain is essential because in some patients, action must be taken immediately and there is not enough time for an exhaustive evaluation. As outlined (see above), such an approach should include a brief initial assessment, a complete clinical history, a thorough physical examination, and targeted laboratory and imaging studies. These steps can usually be completed in less than 1 hour and should be insisted on in the evaluation of most patients. In most cases, it is wise to resist the temptation to rush to the operating room with an incompletely evaluated, unprepared, and unstable patient. Sometimes, the anxiety of the patient or the impatience of the health care providers requesting the surgeon's consultation creates an unwarranted feeling of urgency. Often, however, the anxiety or impatience is on the part of the surgeon and, if indulged, may be a cause of subsequent regret.

Very few abdominal crises mandate immediate operation, and even with these conditions, it is still necessary to spend a few minutes on assessing the seriousness of the problem and establishing a probable diagnosis. Among the most common of the abdominal catastrophes that necessitate immediate operation are ruptured AAAs or visceral aneurysms, ruptured ectopic pregnancies, and spontaneous hepatic or splenic ruptures. The relative rarity of such conditions notwithstanding, it must always be remembered that patients with acute abdominal pain may have a progressive underlying intra-abdominal disorder causing the acute pain

and that unnecessary delays in diagnosis and treatment can adversely affect outcome, often with catastrophic consequences.

SUBACUTE SURGICAL ABDOMEN

When immediate operation is not called for, the physician must decide whether urgent laparotomy or nonurgent but early operation is necessary. Urgent laparotomy implies operation within 4 hours of the patient's arrival; thus, there is usually sufficient time for adequate resuscitation, with proper rehydration and restoration of vital organ function, before the procedure. Indications for urgent laparotomy may be encountered during the physical examination, may be revealed by the basic laboratory and radiologic studies, or may not become apparent until other investigative studies are performed. Involuntary guarding or rigidity during the physical examination, particularly if spreading, is a strong indication for urgent laparotomy. Other indications include increasing severe localized tenderness, progressive tense distention, physical signs of sepsis (e.g., high fever, tachycardia, hypotension, and mental status changes), and physical signs of ischemia (e.g., fever and tachycardia). Basic laboratory and radiologic indications for urgent laparotomy include pneumoperitoneum, massive or progressive intestinal distention, signs of sepsis (e.g., marked or rising leukocytosis, increasing glucose intolerance, and acidosis), and signs of continued hemorrhage (e.g., a falling hematocrit). Additional findings that constitute indications for urgent laparotomy include free extravasation of radiologic contrast material, mesenteric occlusion on angiography, endoscopically uncontrollable bleeding, and positive results from peritoneal lavage (i.e., the presence of blood, pus, bile, urine, or gastrointestinal contents). Acute appendicitis, perforated hollow viscera, and strangulated hernias are examples of common conditions that necessitate urgent laparotomy.

If early operation is contemplated, it may still be prudent to obtain additional studies to obtain information related to the site of the lesion or to associated anatomic pitfalls. In deciding whether to order such studies, it is important to consider not only whether the additional information obtained will increase confidence in the diagnosis but also whether the extra time, expense, and discomfort involved will be justified by the quality and usefulness of the information.⁴³ During a short, defined period of resuscitation, it may be possible to employ CT scanning to identify the location of the inflamed appendix in difficult (i.e., retrocecal or pelvic) locations. Knowing the location of the appendix and its morphology can be helpful in directing the incision in an open operation or determining the most expeditious exposure in a laparoscopic procedure. CT scanning may also be used to identify an atypical site of a visceral perforation (e.g., the proximal stomach, the distal or posterior wall of the duodenum, or the transverse colon), thereby guiding placement of the incision and obviating needless dissection of tissue planes. In the setting of distal bowel obstruction, an expeditious Gastrografin (Bracco Diagnostics, Princeton, NJ) enema or CT scan may alert the surgeon to the possibility of an otherwise undetectable malignancy (e.g., cecal carcinoma causing distal bowel obstruction). In cases in which ischemic bowel is suspected, the site of vascular blockage can be localized by using a CT angiogram imaging protocol. In each of these examples, the information gained may permit the

surgeon to plan the operation, to optimize time spent under anesthesia, and to minimize postoperative discomfort after laparotomy.

The use of preoperative imaging has become increasingly important as an operative planning tool, particularly when laparoscopic approaches are contemplated for management of acute abdominal emergencies. In the 1990s and the first few years of the 21st century, a number of trials were performed to determine whether laparoscopy or open operation should be the approach of choice when the primary clinical diagnosis is acute appendicitis. This topic has been reviewed extensively in the literature^{44–46} and in a 2004 update of a Cochrane meta-analysis.⁴⁷ In some environments, the answer to this question remains unclear.^{48,49} In many settings, however, the current consensus is that uncomplicated appendicitis can be treated laparoscopically, with a clear expectation of less postoperative pain, a shorter hospital stay, and an earlier return to work and regular activities. These advantages, although significant, do not indicate that a laparoscopic approach is to be preferred in all or most clinical settings or that it is necessarily more cost-effective than an open approach.⁴⁷ Laparoscopic appendectomy requires a high level of organization with respect to operating room resources, and this level of organization may be difficult to achieve in institutions where the procedure is not performed regularly (particularly in the middle of the night). In addition, it is not clear whether patients with appendicitis that is complicated by a well-established abscess or bowel obstruction benefit from laparoscopic approaches.

Anatomic considerations also enter into the decision whether to perform the procedure laparoscopically. For instance, it can be very difficult to separate a perforated retrocecal appendix from adherent colon in a safe manner. In many cases, it is prudent not to persist in attempting to extract the appendix without a standard open incision, excellent exposure, and controlled technique. The importance of anatomic considerations underscores the usefulness of preoperative CT in identifying pathologic anatomy, associated abnormalities, and potential pitfalls for either open or laparoscopic approaches.

The advantages of laparoscopy in the management of other abdominal emergencies are less clear-cut. It is important that the surgeon determine not only whether the particular clinical scenario is amenable to a laparoscopic approach but also whether the experience of the entire team and that of the institution as a whole are sufficient for what may be an advanced procedure performed in an acute situation. With this caveat in mind, various investigators have demonstrated that laparoscopy can be employed safely and with good clinical results in selected patients with perforated peptic ulcers.^{50–54} Two prospective, randomized, controlled trials comparing open repair of perforated peptic ulcers with laparoscopic repair found that the latter was safe and reliable and was associated with shorter operating times, less postoperative pain, fewer chest complications, shorter postoperative hospital stays, and earlier return to normal daily activities than the former.^{52,54}

ACUTE ABDOMINAL PAIN REQUIRING OBSERVATION

It is widely recognized that of all patients admitted for acute abdominal pain, only a minority require immediate or urgent operation.^{2,12} It is therefore both cost-effective and prudent to adopt a system of evaluation that allows for thought and investigation before definitive treatment in all

patients with acute abdominal pain except those identified early on as needing immediate or urgent laparotomy. The traditional wisdom has been that spending time on observation opens the door for complications (e.g., perforating appendicitis, intestinal perforation associated with bowel obstruction, or strangulation of an incarcerated hernia). However, clinical trials evaluating active in-hospital observation of patients with acute abdominal pain of uncertain origin have demonstrated that such observation is safe, is not accompanied by an increased incidence of complications, and results in fewer negative laparotomies.⁵⁵ Many institutions now employ CT scanning liberally in patients with uncertain diagnoses; this practice should greatly minimize the incidence of diagnostic failures or delays in patients with acute conditions necessitating surgical intervention.³²

The initial resuscitation and assessment are followed by appropriate imaging studies and serial observation. Specific monitoring measures are chosen (e.g., examination of the abdomen, measurement of urine output, a WBC count, and repeat CT scans), and end points of therapy should be identified. Active observation allows the surgeon to identify most of the patients whose acute abdominal pain is caused by NSAP or by various specific nonsurgical conditions. It must be emphasized that active observation involves more than simply admitting the patient to the hospital and passively watching for obvious problems: it implies an active process of thoughtful, discriminating, and meticulous reevaluation (preferably by the same examiner) at intervals ranging from minutes to a few hours, complemented by appropriately timed additional investigative studies.

A major point of contention in the management of patients with acute abdominal pain is the use of narcotic analgesics during the observation period. The main argument for withholding pain medication is that it may obscure the evolution of specific findings that would lead to the decision to operate. The main argument for giving narcotic analgesics is that in a controlled setting where patients are being observed by experienced clinicians, outcomes are not compromised and patients are more comfortable.⁵⁶ It has also been suggested that providing early pain relief may allow the more critical clinical signs to be more clearly identified⁵⁷ and that severe pain persisting despite adequate doses of narcotics suggests a serious condition for which operative intervention is likely to be necessary.

In my view, the decision whether to provide or withhold narcotic analgesia must be individualized.⁵⁸ The current consensus is that for most patients undergoing evaluation and observation for acute abdominal pain, it is safe to provide medication in doses that would “take the edge off” the pain without rendering the patient unable to cooperate during the observation period. It may be especially desirable to provide medication in a manner that allows the patient to be comfortable while lying in the CT scanner. In these cases, the goal of pain relief is to make it easier to obtain accurate information that will facilitate and expedite the diagnosis and the development of a treatment plan. Given the high diagnostic yield and accuracy of the new generation of CT scanners, it is generally safe to provide pain medication while obtaining the diagnosis.

On occasion, however, reflex administration of pain medication solely with the aim of relieving pain may be undesirable or even harmful. For example, in situations for which advanced

imaging is unavailable, physical examination may be so crucial to decision making that any risk of obscuring important physical findings is deemed unacceptable; therefore, pain medication should be withheld. In addition, narcotic analgesia should be used cautiously in patients with acute intestinal obstruction when strangulation is a concern.⁵⁹ These patients present with abdominal pain that is out of proportion to the physical findings, a syndrome whose differential diagnosis includes acute intestinal ischemia, pancreatitis, ruptured aortic aneurysm, ureteral colic, and various medical causes (e.g., sickle cell crisis and porphyria). A period of resuscitation and evaluation, in conjunction with advanced imaging studies (e.g., CT), may then yield a tentative diagnosis of intestinal obstruction caused by adhesions (e.g., if the patient has a history of abdominal surgery and no evidence of herniation or obturation) without evidence of bowel ischemia. In this setting, the decision whether to admit the patient for observation rather than immediate operation depends on the extent to which the surgeon is confident that the obstruction is not a “closed loop.”⁵⁹ However, within a relatively short period (perhaps 4 to 24 hours), the surgeon must determine whether any indications for operation will arise, and the main parameters for observation include the WBC count, the urine output, and the development of peritoneal findings. In such cases, it may well be prudent to withhold pain medication until there is a high level of confidence that the timing of surgery will not be delayed.

A final point is that over the course of a 24- to 48-hour observation period, the patient’s condition may neither deteriorate nor improve, and supplemental investigation may be considered. Diagnostic laparoscopy has been recommended in cases in which surgical disease is suspected but its probability is not high enough to warrant open laparotomy.^{60,61} It is particularly valuable in young women of childbearing age, in whom gynecologic disorders frequently mimic acute appendicitis.^{62–64} A 1998 report showed that diagnostic laparoscopy had the same diagnostic yield as open laparotomy in 55 patients with acute abdomen; 34 (62%) of these patients were safely managed with laparoscopy alone, with no increase in morbidity and with a shorter average hospital stay.⁶³ Diagnostic laparoscopy has also been shown to be useful for assessing acute abdominal pain in acutely ill patients in the intensive care unit.^{60,65}

In patients with AIDS,^{66,67} a number of unusual diagnoses may be related to or coincident with an episode of abdominal pain. The differential diagnosis includes lymphoma, Kaposi sarcoma, tuberculosis and variants thereof, and opportunistic bacterial, fungal, and viral (especially cytomegaloviral) infections. Laparoscopy has been used for the purposes of diagnosis, biopsy, and treatment in patients with an established AIDS diagnosis who manifest acute abdominal pain syndrome.^{66,67} The complication rate and mortality associated with surgery are related to the underlying illness, and outcomes have improved steadily over the years.⁶⁸ It is important to note that patients who are infected with HIV but have no clinical manifestations of AIDS are evaluated and managed in the same fashion as patients without HIV infection when they present with acute abdominal pain. The differential diagnosis and the outcomes are essentially no different, unless there are reasons to think that the new onset of pain in an HIV-infected patient is a manifestation of AIDS.^{58,68}

Subacute or Chronic Relapsing Abdominal Pain: Role of Outpatient Evaluation and Management

For every patient who requires hospitalization for acute abdominal pain, at least two or three others have self-limiting conditions for which neither operation nor hospitalization is necessary. Much or all of the evaluation of such patients, as well as any treatment that may be needed, can now be completed in the outpatient department. To treat acute abdominal pain cost-effectively and efficiently, the surgeon must be able not only to identify patients who need immediate or urgent laparotomy or laparoscopy but also to reliably identify those whose condition does not present a serious risk and who therefore can be managed without hospitalization. The reliability and intelligence of the patient, the proximity and availability of medical facilities, and the availability of responsible adults to observe and assist the patient at home are factors that should be carefully considered before the decision is made to evaluate or treat individuals with acute abdominal pain as outpatients.

SUSPECTED NONSURGICAL ABDOMEN

Numerous disorders cause acute abdominal pain but do not call for surgical intervention. These nonsurgical conditions are often extremely difficult to differentiate from surgical conditions that present with almost indistinguishable characteristics.² For example, the acute abdominal pain of lead poisoning or acute porphyria is difficult to differentiate from the intermittent pain of intestinal obstruction in that marked hyperperistalsis is the hallmark of both. As another example, the pain of acute hypolipoproteinemia may be accompanied by pancreatitis, which, if not recognized, can lead to unnecessary laparotomy. Similarly, acute and prostrating abdominal pain accompanied by rigidity of the abdominal wall and a low hematocrit may lead to unnecessary urgent laparotomy in patients with sickle cell anemia crises. To further complicate the clinical picture, cholelithiasis is also often found in patients with sickle cell anemia.

In addition to numerous extraperitoneal disorders [see Table 2], nonsurgical causes of acute abdominal pain include a wide variety of intraperitoneal disorders, such as acute gastroenteritis (from enteric bacterial, viral, parasitic, or fungal infection), acute gastritis, acute duodenitis, hepatitis, mesenteric adenitis, salpingitis, Fitz-Hugh–Curtis syndrome, mittelschmerz, ovarian cyst, endometritis, endometriosis, threatened abortion, spontaneous bacterial peritonitis, and tuberculous peritonitis. As noted (see above), acute abdominal pain in immunosuppressed patients or patients with AIDS is now encountered with increasing frequency and can be caused by a number of unusual conditions (e.g., cytomegalovirus enterocolitis, opportunistic infections, lymphoma, and Kaposi sarcoma), as well as by the more usual ones.

Although such disorders typically are not treated by operative means, operation is sometimes required when the diagnosis is uncertain or when a surgical illness cannot be excluded with confidence. In such cases, laparoscopy can be very helpful, permitting relatively complete and systematic exploration without involving the potential morbidity or the longer postoperative recovery and rehabilitation period associated with open exploration.^{69–72} From the surgeon’s point of view, an optimal outcome for laparoscopic exploration in these settings is one in

which a diagnosis is established by means of visualization, with or without biopsy, and in which symptoms improve as a consequence of a therapy directed by the laparoscopic findings. Overall, candidate lesions—including appendiceal pathology (e.g., chronic appendicitis or carcinoid tumor), adhesions, hernias, endometriosis, mesenteric lymphadenopathy—are identified in about 50% of cases, with pelvic adhesions being the most common finding. From the patient's point of view, however, establishing a precise diagnosis may not be particularly critical, and symptomatic improvement, by itself, may suffice to render the outcome successful. Indeed, a number of reports have emphasized that laparoscopy often leads to improvement in symptoms even if no lesion is identified or treated.^{69,70} This point may be illustrated by considering pelvic adhesions.

Given the frequency with which laparoscopic exploration identifies pelvic adhesions, adhesiolysis might be expected to alleviate abdominal pain in many cases. However, it is unclear whether adhesiolysis is therapeutically beneficial when there is no firm evidence that the adhesions are contributing to the pain syndrome. In one prospective, randomized trial, 100 patients with laparoscopically identified adhesions were randomly allocated to either a group that underwent adhesiolysis or one that did not.⁷³ Both groups reported substantial pain relief and a significantly improved quality of life, but there were no differences in outcome between them, which suggested that the benefit of laparoscopy could not be attributed to adhesiolysis. Longer-term studies also failed to support the hypothesis that pelvic adhesions are responsible for chronic pelvic pain.⁷⁴ However, in a study conducted concurrently with the aforementioned randomized trial, 224 consecutive patients underwent laparoscopically assisted adhesiolysis, and 74% of the 224 obtained short-term relief.⁷⁵ Factors that contributed to a successful outcome were gender, age, and adhesions severe enough to have led to inadvertent

enterotomy and a consequent need for open exploration. It may, therefore, be possible to identify specific subgroups that would benefit from the addition of adhesiolysis to exploratory laparoscopy.

A similar issue arises with respect to pathologic conditions of the appendix—namely, whether appendectomy should be performed when no other source of the abdominal pain can be identified. Early enthusiasm for appendectomy in patients with chronic right lower quadrant pain was sparked by observations of acute or chronic inflammation in specimens that seemed visibly normal.^{76,77} In subsequent reports, however, this enthusiasm was tempered by the recognition that these pathologic findings were not very prevalent and that appendectomy did not always reduce the pain.^{78,79} No randomized trial of appendectomy for chronic abdominal pain has been performed in a clearly defined patient group, as has been done for adhesiolysis.⁷³

At present, the surgeon can only use his or her best judgment as to the likelihood that a given episode of abdominal pain may originate from a set of visible adhesions or a visually normal appendix. It should be remembered that unnecessary or potentially meddlesome interventions are always best avoided; however, it should also be remembered that failure to alleviate chronic relapsing abdominal pain will lead to a program of chronic pain management, including long-term management with potentially addictive and enervating agents. Thus, if adhesiolysis or appendectomy can be performed with the expectation of low morbidity and without conversion to laparotomy, it seems reasonable to perform these procedures during laparoscopy if no other source of pain can be identified.

Financial Disclosures: None Reported.

2 ABDOMINAL MASS

Wilbur B. Bowne, M.D., and Michael E. Zenilman, M.D., F.A.C.S.

Evaluation of an Abdominal Mass

Abdominal masses are commonly addressed by surgeons, as well as by members of many clinical subspecialties. In terms of clinical importance, abdominal masses cover a broad spectrum: some have few or no apparent consequences, others significantly impair quality of life, and still others represent severe conditions that are associated with poor outcomes and high mortalities. For each patient, therefore, it is essential to formulate a management approach that is tailored to the particular clinical situation. Effective decision-making in this regard involves establishing the correct diagnosis, introducing an effective treatment plan, eliminating risks and complicating factors, initiating preventive measures, and determining the prognosis.

The history of the abdominal mass in the medical literature is ancient, dating back to the Egyptians. The varied differential diagnosis of such masses was discussed in the Papyrus Ebers (ca. 1500 B.C.).¹ Egyptian medical scholars kept detailed notes chronicling conditions encountered and describing methods of abdominal examination that were based on studies of basic anatomy and embalming practices. Centuries later, in his *Book of Prognostics*, the Greek physician Hippocrates (ca. 400 B.C.) discussed the prognostic significance of various types of abdominal masses:

The state of the hypochondrium is best when it is free from pain, soft, and of equal size on the right side and the left. But if inflamed, or painful, or distended; or when the right and left sides are of disproportionate sizes; all of these appearances are to be dreaded. A swelling in the hypochondrium, that is hard and painful, is very bad.... Such swellings at the commencement of disease prognosticate speedy death. Such swellings as are soft, free from pain, and yield to the finger, occasion more protracted crises, and are less dangerous than others.²

Along with the basic methods of clinical evaluation known since antiquity, the modern surgeon has an armamentarium of sophisticated diagnostic studies that aid in the detection, diagnosis, and appropriate treatment of abdominal masses.

In this chapter, we begin with essential definitions and anatomic considerations and then outline our fundamental approach to evaluating patients with an abdominal mass, which integrates the clinical history, the physical examination, and various investigative studies. In particular, we address current developments in investigative techniques, including radiographic and molecular imaging studies that facilitate anatomic evaluation, diagnosis, and determination of the biologic significance of the abdominal mass; we also address minimally invasive diagnostic interventions. Throughout, we emphasize an algorithmic, evidence-based approach to detection and evaluation of abdominal masses. Specific perioperative and operative strategies for addressing particular diagnoses are outlined in other chapters.

Clinical Evaluation

In general, the term abdominal mass refers to a palpable mass that lies anterior to the paraspinal muscles in a region bordered by the costal margins, the iliac crests, and the pubic symphysis. One method of description divides the abdomen into nine areas: epigastric, umbilical, suprapubic, right hypochondriac, left hypochondriac, right lumbar, left lumbar, right inguinal, and left inguinal.³ Our preferred method

divides the abdominal cavity into four quadrants—right upper, right lower, left upper, and left lower—and makes specific reference to the epigastrium and the hypogastrium as necessary. This method of description also includes masses discovered within the retroperitoneum and the abdominal wall. For practical purposes, the abdominal wall begins from the diaphragm superiorly and continues inferiorly to the pelvic cavity through the pelvic inlet. The anterior, posterior, and lateral boundaries of the abdominal wall should be familiar to surgeons. Further anatomic detail is available in other sources.^{4,5}

A sound understanding of the normal anatomy in each abdominal quadrant is essential for the evaluation of the abdominal mass. Particular abnormalities tend to be associated with particular regions or quadrants of the abdomen, and these associations should be considered first in the differential diagnosis. Commonly, an abnormal enlargement or mass in the abdomen comes to the clinician's attention in one of three ways: it is detected and reported by the patient, it is discovered by the clinician on physical examination, or it is noticed as an unrelated incidental finding on a radiographic study. Subsequent clinical decision making is then influenced by whether the lesion is intra-abdominal, pelvic, retroperitoneal, or situated within the abdominal wall. In certain cases, a prompt diagnosis can be made after the physical examination, with no further investigation required; obesity, ascites, pregnancy, hernias, infection or abscess, cysts, and lipomas are examples of conditions that can generally be diagnosed at this point.

Of the various factors that go into making the diagnosis and implementing therapy, clinical experience is undoubtedly paramount. Nevertheless, even the most experienced physicians are subject to some degree of clinical inaccuracy. A randomized study from 1981 found that even when experienced clinicians were certain about the presence of a mass, there was still an appreciable (22%) chance that further investigation would not reveal any abnormality.⁶ The evaluation of abdominal masses continues to pose many clinical challenges for the surgeon. There is no magical

Evaluation of an Abdominal Mass

formula for mastering the necessary diagnostic skills; the closest thing to such a formula is an approach that combines knowledge and application of fundamental anatomic principles with continuous development and appropriate utilization of new diagnostic modalities. For accurate assessment of the origin and character of the abdominal mass, it is essential to possess a thorough understanding of the normal anatomy, the anatomic variations that may be observed, and the distortions that may be caused by the various potential disease processes. As has been said of many professions besides surgery, "You must know the territory." Ultimately, whether a correct diagnosis calls for further intervention or for referral to colleagues with complementary technical expertise depends on the experience of the practitioner.

Fundamental to the successful diagnosis of any abdominal mass are a detailed medical and surgical history and a meticulous physical examination (see below).

HISTORY

Establishing a solid surgeon-patient relationship is vital for building patient trust and confidence, particularly during a period of great uncertainty and vulnerability in the patient's life. Accordingly, our philosophy in dealing with an abdominal mass is to evaluate the patient first and then consider radiographic and laboratory studies if the initial assessment does not yield a diagnosis. A careful and methodical clinical history should be taken that includes all factors pertaining to the lesion. Information about the lesion's mode of onset, duration, character, chronology, and location should be obtained, as well as confirmation of the presence or absence of associated symptoms.

Interviewing strategies for collecting clinical data may vary from surgeon to surgeon.⁷ For example, some prefer to conduct a clinical history while sitting rather than standing because this posture tends to suggest the absence of undue haste and the presence of appropriate concern and empathy. A focused, comprehensive interview usually provides all the information necessary for making the correct diagnosis. Our practice is to start by asking nondirective questions—for example, "When did you first notice the mass on your left side?" or "How long did you experience this pain in your abdomen?" It is important to allow patients to describe the history in their own words. It is also important to avoid questions with a built-in degree of bias—for example, "Didn't you know the mass was on your left side?" or "The pain must have been there for some time?" Such questions can lead to biased answers that may misrepresent the chronology or the true natural history of the disease. In most cases, we then proceed to ask questions designed to elicit more specific information (e.g., previous operations, previous medical conditions or therapies, family medical history, or recent travel). It is sometimes necessary to fill in the details by asking direct questions about particular points not already mentioned by the patient. For example, an inquiry regarding gastrointestinal symptoms associated with the abdominal mass may be either non-specific (e.g., concerned with nausea, vomiting, diarrhea, or constipation) or specific (e.g., concerned with jaundice, melena, hematochezia, hematemesis, hematuria, or changes in stool caliber). Non-GI symptoms (including urologic, gynecologic or obstetric, vascular, and endocrinologic symptoms) should not be overlooked. A history of surgery, trauma, or neoadjuvant or adjuvant cancer therapy may be diagnostically important.⁸ For instance, the presence of an abdominal mass representing recurrent cancer raises important clinical questions concerning the advisability of additional therapy or palliative measures, which may carry significant morbidity and mortality.⁹⁻¹²

DIFFERENTIAL DIAGNOSIS

For practical purposes, the differential diagnosis for an abdominal mass is divided into categories corresponding to the anatomic divisions of the abdomen (i.e., the four quadrants, the epigastrium, and the hypogastrium) [see *Figure 1*]. The challenge for the modern surgeon is how to narrow down the diagnostic possibilities while avoiding needlessly extensive and expensive evaluations. To accomplish this goal with efficiency, the surgeon must draw both on his or her own reservoir of fundamental knowledge and on the available patient data (e.g., age, gender, associated symptoms, and comorbidities).

After obtaining a thorough clinical history, the surgeon should be able to generate a differential diagnosis. The physical examination may then help confirm or rule out diagnostic possibilities. For example, the presence or absence of pain or tenderness may distinguish an inflammatory or nonneoplastic process from a neoplastic one (e.g., cholecystitis from Courvoisier gallbladder or, perhaps, diverticulitis from carcinoma of the colon). Likewise, the acuteness of the condition may help eliminate diagnostic possibilities, as when an incarcerated abdominal wall hernia is distinguished from a lipomatous mass. So too may the nature of the process, as when a pulsatile mass such as an aneurysm is distinguished from a nonpulsatile one such as a hematoma or a cyst.

Masses of the abdominal wall commonly are subcutaneous lipomas, and care should be taken to differentiate them from neoplastic lesions such as desmoid tumors,¹³ dermatofibrosarcoma protuberans (DFSP),¹⁴ and other related¹⁵ or nonrelated tumors.^{16,17} When an abdominal mass is associated with uncommon or unexpected findings, the surgeon must be alert to the possibility of an uncommon or unexpected disease process.^{18,19} It remains true, however, that knowledge of the most common disease processes associated with region-specific abdominal masses, combined with familiarity with the characteristic signs and symptoms, is the foundation of the clinical assessment of such masses.

PHYSICAL EXAMINATION

The physical examination plays an essential role in the evaluation and workup of an abdominal mass. Current investigative studies are also important in this setting, but all too often, clinicians become overly reliant on various imaging modalities, sometimes overlooking the importance of a careful and thorough examination. Such overreliance can increase the chances of missing subtle physical findings—such as an enlarged lymph node, subcutaneous irregularity, or referred pain—that could have a significant effect on the management of the abdominal mass. Our practice in examining patients with an abdominal mass is to follow an organized, systematic approach consisting of inspection, auscultation, percussion, and palpation, in that order. More detailed discussions of these specific maneuvers are available elsewhere.²⁰

The physical examination has three main objectives. First, the examiner must evaluate the patient's condition as it directly or indirectly relates to the mass (e.g., by noting associated systemic illness, pain, malaise, or cachexia). Second, the examiner must assess the acuteness of the patient's condition (e.g., by determining whether a left upper quadrant mass is likely to be a ruptured spleen or simply a long-standing mass in the abdominal wall), which will dictate whether the next step is immediate treatment or further evaluation. Third, the examiner must carefully examine each abdominal quadrant, assessing both normal and abnormal anatomic relations as possible sources of the presumed mass.

How to distinguish a normal abdominal mass or swelling from an abnormal one remains a common challenge for the surgeon.

Figure 1 Schema represents differential diagnosis of an abdominal mass by quadrant or region. Fundamental knowledge of normal anatomy and clinical presentations is the basis for distinguishing the various disease processes. Abdominal wall hernia is considered a possibility in every region or quadrant.

Physical findings on examination are sometimes variable and can be affected by factors such as obesity, body habitus, associated medical conditions, and the patient's ability to cooperate. For example, the normal aorta is often palpable within the epigastrium and may be slightly tender; in elderly, asthenic patients, the normal aorta may be mistaken for an aneurysm. Likewise, the cecum and the descending colon, both of which are usually palpable in thin patients (especially when they contain feces), sometimes masquerade as a cancerous mass; subsequent disimpaction causes such "masses" to resolve. Obesity may preclude evaluation of a potential abdominal mass: it can be difficult to identify discrete palpable masses amid the often remarkable adiposity present within the abdominal wall and the surrounding structures. Ascites may also obscure abdominal masses, making examination more problematic. Transient gaseous distention or intestinal bloating occasionally presents a similar problem, but it usually resolves spontaneously, except in cases of intestinal obstruction. Either gastric dilatation or intestinal obstruction may lead to abdominal distention that is severe enough to necessitate nasogastric decompression. Not uncommonly, in women of childbearing age, a lower abdominal mass may represent a gravid uterus. In such cases, a gynecologic examination must be conducted and a pregnancy test performed before further studies are ordered. The multiplicity of potential benign causes notwithstanding, the possibility of a neoplasm (single or multiple) clearly remains a matter of considerable concern in the evaluation of any patient with abdominal distention. A convenient method of recalling the main causes of generalized enlargement or distention of the abdomen is to use the so-called "six Fs" mnemonic device: *Fat, Fluid, Flatus, Fetus, Feces, and Fatal growths.*²¹⁻²³

Palpable or discrete masses should always be localized with respect to the previously described landmarks (see above), and they should, if possible, be described in terms of size, shape, consistency, contour, presence or absence of tenderness, pulsatility, and fixation. Knowledge of the location of the mass in the abdomen shortens the list of structures or organs to be considered and may give insight into the nature and extent of the pathologic process. Frequently, however, the mass's location can only be vaguely outlined, particularly when fluid is present, when the abdomen is tender or tense, or when the patient is obese. Gastric neoplasms, pancreatic neoplasms, colonic neoplasms, sarcomas, pancreatic cysts, and distended gallbladders may be palpable, typically at advanced stages of disease. Recognition of such masses can be facilitated by repeating the abdominal examination after analgesics have been administered or after the patient has been anesthetized in preparation for a procedure.

Working or Presumed Diagnosis

Once a thorough clinical history has been obtained and a careful physical examination conducted, it is usually possible to generate a working diagnosis. Once the working diagnosis has been established, subsequent management is considered in light of its appropriateness for the presumed condition. Sometimes, however, the diagnosis remains unknown even after a comprehensive clinical history and physical examination; in such cases, further studies are required. A wide range of laboratory and imag-

ing studies are now available for establishing the diagnosis. If these studies do not resolve the diagnostic uncertainty, additional procedures, including image-guided percutaneous biopsy, diagnostic laparoscopy, and exploratory laparotomy, may be employed as necessary.

Investigative Studies

Surgeons are in a unique position to care for patients presenting with an abdominal mass and should guide the collaborative management effort and the choice of appropriate investigative studies. It is therefore essential that surgeons be familiar with every available method for efficient and cost-effective diagnosis of an abdominal mass. For any given situation, the selection of investigative studies should be based on the preferences of the patient, the knowledge and judgment of the surgeon, and the capabilities of the institution. In this way, surgeons who practice outside large, specialized referral centers will still be able to provide integral leadership for most disease management efforts arising from the diagnosis of an abdominal mass.

LABORATORY STUDIES

The diagnostic workup of an abdominal mass usually includes laboratory evaluation. If the cause of the mass remains unknown, preliminary laboratory analysis should include a chemistry profile (electrolyte, blood urea nitrogen [BUN], and creatinine concentrations, as well as liver function tests), a complete blood count (CBC) with differential, and urinalysis. An abnormal laboratory value sometimes plays an important role in establishing the identity or pathogenesis of an abdominal mass. For example, an elevated alkaline phosphatase or liver transaminase level may suggest metastasis to the liver. Likewise, an elevated serum amylase concentration may be suggestive of a pancreatic pseudocyst rather than a cystic neoplasm or an adenocarcinoma; however, an elevated total serum bilirubin level (i.e., > 10 mg/dl) may be more suggestive of a malignant process secondary to adenocarcinoma of the pancreatic head or cholangiocarcinoma. Routine testing for occult blood in the stool should not be overlooked. Tumor markers (e.g., carcinoembryonic antigen [CEA], the cancer antigens CA 19-9 and CA 125, and α -fetoprotein [AFP]) may also help differentiate between benign disease processes and malignant ones, distinguish high-level disease from low-level disease, and, in some cases, establish a disease diagnosis (e.g., elevated AFP levels in patients with hepatocellular carcinoma). Similarly, an elevated serum lactate dehydrogenase (LDH) level may prove invaluable in the staging and prognosis of certain diseases (e.g., melanoma) connected with an abdominal mass.²⁴ Furthermore, the ability to distinguish between functional abdominal masses and nonfunctional ones (e.g., adrenal tumors) also has important implications for evaluation and management.

In some cases, when the type of mass remains unknown, needless and expensive laboratory analysis can and should be avoided if it appears that other studies may prove more beneficial.

IMAGING

Diagnostic radiology is a dynamic specialty that has undergone rapid change in conjunction with the ongoing evolution of imaging technology. Not only has the number of imaging modalities increased, but each modality continues to be

improved and refined for use in evaluating abdominal masses. In particular, advances in cross-sectional imaging techniques, such as ultrasonography (US), computed tomography, magnetic resonance imaging, and positron emission tomography (PET), have made it possible to assess these lesions more precisely. Consequently, whenever the surgeon is confronted with the scenario of a clinically suspected or palpable abdominal mass, accurate diagnostic imaging is of paramount importance. The appropriate use of different imaging modalities in the evaluation of the palpable abdominal mass is well described by the American College of Radiology guidelines,^{25,26} which are updated every 6 years.

The use of noninvasive US and CT as first-line procedures for the evaluation of palpable masses has received considerable clinical attention.^{6,27-30} Investigators have found both US and CT to be excellent for affirming or excluding a clinically suspected abdominal mass, with sensitivity and specificity values exceeding 95%. This finding is particularly noteworthy because in only 16% to 38% of patients referred for a suspected abdominal mass will the diagnosis be corroborated by an imaging study.³¹ Both US and CT are also capable of visualizing the organ from which the mass arises: US successfully determines the organ of origin approximately 88% to 91% of the time, and CT does so approximately 93% of the time. Prediction of the pathologic diagnosis of an abdominal mass, however, remains a challenge for both modalities. US correctly predicts the pathologic diagnosis in 77% to 81% of cases, whereas CT suggests the diagnosis in 88% of cases. Further advancements in cross-sectional imaging (e.g., multidetector CT [MDCT] with three-dimensional reconstruction and magnetic resonance angiography [MRA]) and the addition of molecular and functional imaging modalities (e.g., PET) will undoubtedly improve the predictive abilities of CT and US. At any rate, the current state of imaging technology affords clinicians the ability to distinguish benign from malignant processes, to assess tumor biology, and to detect lesions that impose a minimal disease burden. As a consequence, clinicians are more likely to detect clinically occult disease or discover it incidentally.

Employing an integrative assessment approach (which includes clinical history, physical examination, and investigative studies) should lead to more targeted, efficient, and cost-effective strategies for evaluating abdominal masses. For example, the surgeon can correlate the clinical location of the abdominal mass with pertinent findings from the history and laboratory studies to determine which imaging modality is the most expeditious and cost-effective for a given circumstance. Each imaging modality has unique strengths and weaknesses.

Plain Abdominal Radiographs

By definition, a plain film is a radiograph made without the use of an artificially introduced contrast substance.³² Commonly employed for initial surveillance of the abdomen, the plain film still has an important place within the investigative armamentarium. Otherwise known as a KUB (kidney-ureter-bladder) study, this low-cost technique may reveal nonspecific or indirect evidence of an abdominal mass, such as variations in the size and density of an organ or displacement of normal structures or fat planes. Furthermore, the radiolucency of air within the bowel may also prove helpful for recognizing worrisome displacement of viscera as a result of a large abdominal mass. Occasionally, a simple plain radiograph can assist the surgeon in making a specific diagnosis, such as calcified aortic aneurysm, acute gastric distention, fecal impaction, porcelain gallbladder, and certain malignancies [see Figure 2].

Figure 2 Plain abdominal radiograph shows a 10 cm functional left adrenocortical carcinoma. Calcifications creating a rim enhancement are easily identified. The diagnosis was confirmed by means of laboratory analysis and abdominal CT.

Conventional Gastrointestinal Imaging

As a consequence of the technical advances in cross-sectional imaging and endoscopy, conventional GI contrast studies are now largely relegated to more adjunctive roles in the evaluation of abdominal masses. In the upper and middle portions of the abdomen, we occasionally use upper GI studies, small bowel follow-through (SBFT), or enteroclysis to evaluate inflammatory masses (e.g., lesions arising from Crohn disease), masses that are inaccessible to endoscopy, or unusual masses with uncertain diagnoses. For such lesions, we employ single- or double-contrast barium protocols to ensure that significant pathology is not missed; however, these studies are notoriously insensitive and do not provide an opportunity for tissue diagnosis. In the lower portion of the abdomen, barium studies still play a significant role in the evaluation of masses whose history includes GI symptoms (e.g., anemia and weight loss) suggestive of a colonic neoplasm, as well as for evaluating inflammatory masses arising from diverticular disease. In certain cases, we employ a single-contrast barium enema for masses that are causing near-complete obstruction; this study is also helpful for assessing the remaining large bowel for synchronous disease. For small lesions (masses < 1 cm), we typically favor a double-contrast barium enema.

Currently, in the evaluation of an abdominal mass, barium studies are used mainly to complement colonoscopy and CT.

Novel approaches (e.g., CT virtual colonoscopy), in conjunction with advances in cross-sectional imaging, may eventually render conventional GI imaging unnecessary.

Ultrasonography

Compared with other modalities, US has several advantages in the evaluation of suspected abdominal masses, including widespread availability, speed of use, the absence of ionizing radiation, low cost, and the ability to document the size, consistency (solid or cystic), and origin of a mass with real-time images.^{27,33} When directed at solving a specific clinical problem, US generally provides more diagnostic information. Moreover, the necessary equipment can easily be transported to the patient's bedside or another clinical setting; thus, no patient preparation is required, and only minimal patient cooperation is needed.

We consider US indispensable in the assessment of abdominal masses. At the same time, we acknowledge that one disadvantage of US is the extent to which the quality of the results depends on the technical proficiency and diligence of the operator or technician (though this disadvantage can actually become an advantage when personnel are well trained and experienced). In the hands of an inexperienced operator, US may yield inconclusive or untrustworthy results that contribute to delayed diagnosis or even misdiagnosis. In an effort to help minimize this problem, we encourage the surgeons at our institution (who are trained in US) to perform their own studies in the clinic and the operating room. This approach further expedites recognition of disease [see Figure 3], positively influences management, and facilitates operative decision making regarding abdominal masses [see Figure 4].

Another disadvantage of US is its inability to visualize the entire abdominal cavity as a consequence of the acoustic barriers presented by gas-containing structures (e.g., the bowel) and the absorptive interfaces (acoustic shadowing) provided by soft tissue and bone. For optimal visualization of abdominal masses, US should be performed through "acoustic windows" that allow adequate transmission of sound. Accordingly, US is most effective as a tool for evaluating masses in those regions of the abdomen where an acoustic window exists (e.g., the right and left upper quadrants and the

Figure 3 Sagittal ultrasonogram of the pancreas demonstrates a large mass in the pancreatic head of a 71-year-old patient referred for "gallstones" after experiencing a 10 lb weight loss. The mass lies anterior to the inferior vena cava.

Figure 4 (a) Transverse ultrasonogram of the liver of a 72-year-old cirrhotic patient with a hepatitis C infection shows a 4.0 × 3.5 cm hepatoma, nestled between the right and middle hepatic veins and closely apposed to the inferior vena cava. (b) Color Doppler ultrasonogram from the same patient displays blood flow in the middle hepatic vein and the surrounding liver parenchyma. Blood flow toward the transducer is usually displayed in shades of red, whereas blood flow away from the transducer is displayed in shades of blue. Color Doppler ultrasonography allows evaluation of the patency and flow characteristics of the hepatic circulation as it relates to the mass.

pelvis). Fortunately, the shortcomings of US can be compensated for by employing other cross-sectional imaging modalities.

Computed Tomography

At present, helical (spiral) CT is the most efficient and cost-effective imaging modality for the evaluation of abdominal masses.^{6,27,34,35} Unlike US, CT provides cross-sectional images with excellent spatial resolution and exquisite density discrimination that are unaffected by bowel gas, bone, or excessive abdominal fat. CT routinely visualizes the abdominal wall, the viscera, the mesentery, and the retroperitoneum, clearly defining important tissue planes

and delineating the relations between the abdominal mass and adjacent structures [see Figure 5]. Such data are essential for guiding diagnostic procedures, determining whether operative management is indicated, and selecting the optimal operative approach. Although modalities such as MRI, PET, and endoscopic ultrasonography (EUS) have advantages over CT in one area or another, CT continues to be superior overall for assessing abdominal masses and remains our preferred imaging method for this purpose.

The use of contrast during the acquisition of CT scans is vital. Opacification of the bowel enables the examiner to distinguish the abdominal mass from surrounding viscera or other adjacent structures. Contrast-enhanced scans also allow delineation of the relevant vascular anatomy; in fact, CT angiography has now relegated conventional angiography to a minimal role in the evaluation of certain abdominal masses.^{36,37} Triple-phase or multiphase scanning that includes noncontrast images is now recommended. Such scans achieve optimal definition and characterization of liver and pancreatic masses. This achievement is of significant clinical value: state-of-the-art CT imaging of malignant pancreatic masses, as well as of other malignancies, has the potential to improve outcome not only by correctly detecting the mass but also by accurately assessing the extent of disease, thereby helping determine which patients may benefit from surgical management or neoadjuvant therapy [see Figure 6].

The advent of MDCT technology offers the possibility of even better imaging of abdominal masses than standard contrast CT provides. MDCT scanners can image specific organs or masses with 1 mm slices in less than 20 seconds, and the resultant data can be displayed not only as an axial image but also in a three-dimensional representation that includes detailed vascular mapping.³⁵ Studies suggest that MDCT may be the most useful modality for preoperative assessment of the resectability of pancreatic and other abdominal masses.³⁶ MDCT has a sensitivity of 90% and a specificity of 99%, respectively, and it is not observer dependent.

Currently, although MRI (see below) offers unique tissue contrast and inherent multiplanar capabilities for imaging abdominal

Figure 5 CT scan of a 65-year-old man with a large retroperitoneal leiomyosarcoma clearly demonstrates close association of this mass with the right hemiliver, as well as displacement of the inferior vena cava.

Figure 6 CT angiography performed to evaluate vascular invasion in a 58-year-old patient with a pancreatic mass demonstrates nearly complete encasement of the superior mesenteric vein. The superior mesenteric artery is not involved with the mass.

masses, CT has several advantages—high resolution, short scan times, and fast patient throughput—that make it a more widely preferred imaging modality for this purpose.

Magnetic Resonance Imaging

Since its introduction in the mid-1980s, MRI has become one of radiology's great success stories (though, because it still is not as widely available as US or CT, its cost-effectiveness has yet to be determined). Few would dispute the enormous impact MRI has had on our ability to diagnose pathologic conditions of the brain, the spine, and the musculoskeletal system. Whereas MRI has clear advantages over CT in these areas of the body, this is not the case in the abdomen. Nevertheless, there are situations in which MRI

is a better choice than CT for evaluating an abdominal mass. An example is a case in which the use of iodinated contrast material is contraindicated. The extracellular gadolinium chelates used in MRI are very safe and can be given to patients with mild to moderate azotemia without causing renal impairment. MRI has unique characteristics that can be effectively employed to distinguish normal from pathologic tissue in a patient with an abdominal mass.³⁸

Detailed information about the principles and practices of abdominal MRI is beyond the scope of this chapter and is readily available elsewhere.³⁹ A brief technical summary may, however, be worthwhile. The abdomen and its contents are subjected to a momentary radiofrequency pulse, then allowed to return to a state of equilibrium. During the return to equilibrium, the nuclei within each specific tissue will emit specific radiofrequency signals. The strength and type of the emitted signal determine the image intensity. The way in which the different tissues are visually rendered depends on (1) the longitudinal relaxation time (T_1) and the transverse relaxation time (T_2) of the nuclei in the tissues and (2) the method of image weighting employed. By convention, tissues with short T_1 values (such as solid structures) appear bright on T_1 -weighted images, whereas structures with long T_2 values (e.g., fluid-containing tissues) appear bright on T_2 -weighted images. The tissue contrast and multiplanar capabilities of MRI allow surgeons and radiologists to distinguish not only obvious but also subtle differences between abdominal masses and normal anatomy. For example, T_1 -weighted images may be valuable for detecting abdominal masses that contain fluid (e.g., cystic masses or masses containing necrotic tissue), whereas T_2 -weighted images may be useful for characterizing these masses as either benign or malignant [see Figure 7]. Similarly, magnetic resonance cholangiopancreatography (MRCP) uses T_2 -weighted images to distinguish masses with different signal intensities in the pancreas, the liver, and the biliary tract.⁴⁰

Positron Emission Tomography

In 1930, Warburg reported that cancer cells show higher rates of glycolysis than normal cells do.⁴¹ This discovery has stood the

Figure 7 (a) Gadolinium-enhanced, T_1 -weighted MRI shows a large mass that appears dark and well-circumscribed in comparison with the normal-appearing enhanced liver and spleen. This abnormal mass clearly contains some fluid. The fluid-filled stomach also appears dark. (b) T_2 -weighted MRI of the same patient details subtle inhomogeneities characteristic of a malignant mass (less organized appearance with an enhanced necrotic component). Subsequent biopsy showed this mass to be a poorly differentiated adenocarcinoma from recurrent colon cancer.

Figure 8 ^{18}F FDG PET scan demonstrates a large metabolically active non-Hodgkin lymphoma giving rise to an abdominal mass.

test of time and now serves as the theoretical rationale for the use of ^{18}F -fluorodeoxyglucose (^{18}F FDG) PET imaging to assess abdominal masses caused by cancer. Briefly, ^{18}F FDG is a glucose analogue that crosses the cell membrane by sharing the glucose transporter molecules used by glucose. Like glucose, it undergoes phosphorylation by the enzyme hexokinase. The resulting molecule, ^{18}F FDG-6-phosphate, is polar and is unable to cross cell membranes or serve as a substrate for metabolism. The net effect is that ^{18}F FDG both accumulates in and is retained by cancer cells.

The molecular information obtained from PET, as measured by standard uptake values (SUV), allows identification of hypermetabolic (^{18}F FDG-avid) abdominal masses (typically arising from lymphomas, melanomas, or certain GI malignancies [see Figure 8]).⁴² PET may also prove to be an important surrogate modality for distinguishing malignant abdominal masses from benign ones.⁴³ When PET is used alone, it has the disadvantage of being unable to provide sufficient anatomic information to guide biopsy or further therapy. When PET is used with CT in PET/CT fusion imaging, however, the functional advantages of PET and the structural advantages of CT combine to enhance the detection rate for abdominal masses.⁴² If a mass is anatomically evident but metabolically inactive, it will be detected by CT. If it shows increased glycolysis but few or no CT abnormalities, it will be detected by PET. The apparent advantages of PET/CT notwithstanding, prospective, randomized validation is necessary before the widespread application of this approach to the evaluation of abdominal masses can be justified. At present, the use of PET/CT is mostly restricted to large tertiary referral centers.

BIOPSY

In many cases, the pathologist is the surgeon's greatest teacher. Despite the surgeon's most strenuous efforts, the biology of the disease or lesion will inevitably dictate the outcome. Nowhere is this statement more true than in the evaluation of the abdominal mass, and its truth becomes increasingly evident as ongoing refinements in molecular diagnosis permit ever more sophisticated discrimination among different tumor types and their respective behaviors.⁴⁴ Aside from the treatment of lymphoma, in which the surgeon is frequently called on to provide technical assistance in obtaining tissue for diagnosis, the decision whether to perform a biopsy (as well as when and how to do so) rests on the surgeon's understanding of the probable disease. For example, surgeons who treat pancreatic cancer usually proceed to surgery without biopsy if the evidence for malignancy is strong. In other cases, biopsy is performed to confirm what is already suspected on the basis of clinical and radiographic findings. Moreover, establishing the type of tumor or mass present has important implications for the use of neoadjuvant or adjuvant therapy, as well as for the planning of the surgical approach. We view the biopsy of an abdominal mass as the first stage of surgery. This procedure, though seemingly innocuous, has the potential to contaminate tissue planes and must therefore be performed carefully. Accordingly, in order to make the appropriate choice when confronted with an abdominal mass, the surgeon must possess a thorough understanding of the various methods of obtaining an accurate and safe biopsy. Factors related to the size and location of the abdominal mass, as well as factors related to institutional preference and experience, may influence the choice of biopsy technique.

Image-Guided Percutaneous Biopsy

The value of image-guided percutaneous biopsy in the evaluation of the abdominal mass is well established.^{45,46} In practice, the procedure begins with identification of the mass by means of a cross-sectional imaging modality such as US, CT, or MRI. Often, three-dimensional imaging reconstructions are generated to detail the relations of the abdominal mass to the surrounding anatomy. Once the mass is identified, decisions are made regarding the safest approach and the most appropriate technique. The biopsy needle is then inserted percutaneously under the guidance of US, CT, or MRI. The choice among the different modalities depends on several factors, including the size and location of the mass, the surgeon's judgment regarding which method is best in the circumstances, and the availability of the various modalities at a particular institution. The most important consideration, however, is the personal preference and experience of the radiologist performing the biopsy. We favor either US or CT, both of which yield good results.

In general, we prefer US-guided biopsy for large, superficial, and cystic masses. This technique is also appropriate for lesions lying at moderate depths in thin to average-size persons. In some cases, US can be employed to guide biopsy of small, deep, and solid abdominal masses; however, US-guided biopsy of these deep-seated masses (as well as of masses in obese patients) often proves difficult because of inadequate visualization resulting from sound attenuation in the soft tissues. Similarly, lesions located within or behind bone or gas-filled bowel cannot be easily visualized (a consequence of the nearly complete reflection of sound from bone or air interfaces).

Figure 9 In a percutaneous biopsy of a large abdominal mass, CT guidance is a reliable means of determining the direction and depth of the needle.

US possesses several strengths as a guidance modality for percutaneous biopsy. It is readily available, inexpensive, and portable, and it provides guidance in multiple transverse, longitudinal, or oblique planes. Moreover, it offers real-time visualization of the needle tip as it passes through tissue planes into the target area,⁴⁷ thereby allowing the surgeon to place the needle precisely and to avoid important intervening structures. In addition, color flow Doppler imaging can help prevent complications of needle placement by identifying the blood vessels involved with the mass, as well as any vessels lying within the needle path. Because of its real-time capabilities, US guidance has the potential to allow quicker, more accurate, and less expensive biopsies than CT guidance does.⁴⁸ In theory, any mass that is well visualized with US should be amenable to US-guided biopsy. In practice, however, this modality remains best suited for superficial to moderately deep abdominal masses and for patients with a thin to average body habitus.

The utility of US notwithstanding, CT remains indispensable at our institution as a guidance method for percutaneous biopsy of most regions in the body. It is particularly useful when an abdominal mass is in a location that is inaccessible to US as a result of bowel gas or body habitus. In the abdomen, CT provides excellent spatial resolution of all structures between the skin and the mass, regardless of body habitus or lesion depth, and it provides an accurate image of the needle tip. We favor CT guidance for abdominal masses that are located deep in the abdomen or in the retroperitoneum. The only limitation of CT in this setting is that it does not offer continuous visualization of the needle during insertion and biopsy. In most cases, however, CT guidance can reliably establish the direction and depth of the needle [see Figure 9].

Numerous different needles, covering a broad spectrum of calibers, lengths, and tip designs, are commercially available for use in percutaneous image-guided fine-needle aspiration (FNA) biopsy. For convenience, these needles can be grouped into two main size categories: small caliber (20 to 25 gauge) and large caliber (14 to 19 gauge). Small-caliber needles are used primarily for cytologic analysis but may also be employed to obtain small pieces of tissue for histologic analysis. The flexible shaft of small-caliber needles allows them to be passed with minimal risk of tissue or organ

laceration or of damage from tearing. Such needles are often used to confirm tumor recurrence or metastasis in patients with a pathologically confirmed primary malignancy. Large-caliber needles are typically used to obtain greater amounts of material for histologic or cytologic analysis.⁴⁹ In practice, the choice of a biopsy needle is often influenced by whether the suspected pathology is benign or malignant. For example, large-caliber needles may be necessary to obtain a sufficiently large histologic specimen when certain types of malignancies (e.g., lymphoma) are suspected. When an inflammatory mass is suspected and material is needed for culture, however, a small-caliber needle may be preferred.

Additional considerations for image-guided biopsy include the accuracy, safety, and potential complications of the proposed technique. These considerations are essential for an evidence-based approach to diagnosis of an abdominal mass.

The reported accuracy of US-guided biopsy ranges from 66% to 97%. The location, size, and histologic origin of the abdominal mass appear to influence the diagnostic accuracy of the procedure.⁴⁷ In a series that included 126 consecutive small (< 3 cm) solid masses distributed among various anatomic locations and histologic types, US-guided biopsies showed an overall accuracy of 91%.⁴⁷ Biopsy results improved as the size of the mass increased: accuracy rose from 79% in masses 1 cm or less in diameter to 98% in masses 2 to 3 cm in diameter. The accuracy of US-guided biopsy in the liver, where most of the biopsies were performed, exceeded 96%. Another study found US-guided biopsy to be 91% accurate for abdominal masses less than 2.5 cm in diameter.⁵⁰ Two organ-specific reviews concluded that US-guided biopsy of hepatic masses had an accuracy of 94%⁵¹ and that US-guided biopsy of pancreatic masses had an accuracy of 95%.⁵²

The reported accuracy of CT-guided biopsy ranges from 80% to 100%. As with US-guided biopsy, the size, location, and histologic origin of the mass influence the results.⁵³⁻⁵⁵ In a study of 200 consecutive CT-guided needle biopsies, the overall accuracy for all sites biopsied was 95%. The reported organ-specific accuracy was as follows: kidneys, 100%; liver, 99%; retroperitoneum, 87.5%; and pancreas, 82%.⁵⁶ In a prospective study of 1,000 consecutive CT-guided biopsies, the reported sensitivity was 91.8% and the specificity 98.9%.⁵⁵ At our institution, as well as others, CT-guided biopsy is now considered a reliable tool for the diagnosis and classification of malignant abdominal lymphomas.⁵⁷

The safety of image-guided percutaneous biopsy is well documented. Several large multi-institutional reviews reported major complication rates ranging from 0.05% to 0.18% and mortalities ranging from 0.008% to 0.031%.⁵⁸⁻⁶⁰ A large prospective study of 3,393 biopsies (1,825 US-guided; 1,568 CT-guided) documented an overall mortality of 0.06%, a major complication rate of 0.34% (0.3% with US; 0.5% with CT), and a minor complication rate of 2.9% (2.4% with US; 3.3% with CT).⁴⁷ Procedure-related morbidity and mortality appear to be largely unaffected by whether a small-caliber or a large-caliber biopsy needle is used. A review of 11,700 patients who underwent percutaneous abdominal biopsy with 20- to 23-gauge needles found an overall complication rate of only 0.05% and an overall mortality of only 0.008%.⁵⁸ A single-institution review of 8,000 US-guided needle biopsies performed with both small- and large-caliber needles reported equivalent results: a major complication rate of 0.187% and a mortality of 0.038%.⁶¹ Of the rare major complications that occur, hemorrhage is the most frequently reported; pneumothorax, pancreatitis, bile leakage, peritonitis, and needle track seeding may also develop.

Needle-track seeding remains an important theoretical consideration when an abdominal mass appears likely to be malignant. According to some investigators, percutaneous needle biopsy has

the potential to seed between 10^3 to 10^4 tumor cells into the needle track.^{62,63} Nevertheless, tumor dissemination after percutaneous biopsy remains exceedingly rare: with fewer than 100 cases reported in the world literature, it has an estimated frequency of 0.005%,⁶⁴⁻⁶⁶ mostly occurring after biopsy of pancreatic, hepatic, or retroperitoneal masses. Poorly planned biopsies of malignant abdominal masses have the potential to exert adverse effects on subsequent surgery and to compromise local tumor control; fortunately, such negative consequences remain rare.

EUS-Guided Imaging and Biopsy

EUS provides unique imaging information because it involves the close apposition of a high-frequency ultrasound transducer, called an echoendoscope (whereby image resolution is directly related to frequency), to the structures being studied. As a result, it can delineate abdominal masses and associated structures with greater anatomic detail than standard transcutaneous ultrasonography can. In general, EUS-guided biopsy is well suited for abdominal masses that are too small for visualization by means of other cross-sectional imaging modalities or that are inaccessible to percutaneous biopsy.⁶⁷ The most frequently used EUS device is the radial echoendoscope, which creates a 360° tomographic image perpendicular to the scope. The circumferential view obtained with this instrument facilitates orientation and therefore is more efficient for diagnostic imaging. Alternatively, the linear-array echoendoscope, which generates an image parallel to the shaft of the scope, may be used. This instrument produces high-quality gray-scale images, as well as color and duplex images. EUS-guided biopsy with a linear scanning system offers clear and consistent visualization of the biopsy needle along its entire path in real time, with excellent delineation of intervening tissues and without any interference from intestinal gas.

EUS has proved to be superior to other cross-sectional imaging modalities for detection and staging of pancreatic, gastric, and esophageal masses.⁶⁸⁻⁷¹ For instance, in a patient with a pancreatic mass, EUS not only identifies the size of the mass and the peripancreatic lymph nodes but also delineates the relations of these structures to major blood vessels. EUS has also proved to be helpful in selecting patients for various neoadjuvant protocols. Furthermore, the availability of high-frequency catheter-based intraductal ultrasonography (IDUS) now enables surgeons to visualize masses within the biliary tree and obtain biopsy specimens from them.⁷²

Advantages notwithstanding, EUS technology has several important limitations. As with all forms of ultrasonography, a substantial period is required before the operator achieves proficiency. EUS is highly operator dependent; when it is done by an inexperienced operator, the potential exists for serious misinterpretations. For example, if an operator obtains only one view of a mass in the head of the pancreas, the mass may appear to be invading vascular structures when it is not actually doing so. In the evaluation of pancreatic masses around vessels, the operator should always obtain multiple views. It cannot be overemphasized that EUS and EUS-guided biopsy require personnel with sufficient experience and skill in both ultrasonography and endoscopy.

EUS is frequently employed for diagnosis and staging of upper GI malignancies. In a large single-institution study of 267 pancreatic masses that were sampled by means of EUS-guided biopsy and subsequently resected, the overall diagnostic accuracy was 95.6%, the sensitivity was 94.6%, and the specificity was 100%.⁷³ In studies of gastric and esophageal masses, diagnostic accuracy was related to the location of the biopsy,⁷⁴ the histology of the dis-

ease,⁷⁵ and the number of samples obtained. In one series that included more than 200 patients with esophageal or gastric masses, a diagnosis was made in 70% of patients after the first biopsy, 95% of patients after the fourth biopsy, and 98.9% of patients after the seventh biopsy.⁷⁶ Several other studies have confirmed the high sensitivity and specificity of EUS-guided biopsy (especially for the diagnosis of extraluminal abdominal masses) and verified the safety of the procedure (reported complication rates range from 0.3% to 2%).^{68-71,77} It is worth noting that in the resection of a potentially curable abdominal mass, concern about needle-track contamination is obviated when the path of the needle is removed as part of the surgical specimen (as in pancreaticoduodenectomy for a pancreatic head mass or gastrectomy for a stomach mass).

We consider EUS-guided biopsy for the diagnosis of masses that are not readily accessible to percutaneous biopsy, on the grounds that it can obviate more invasive procedures (e.g., laparoscopy and laparotomy). In a 10-year study of the impact of EUS on patient management, 86% of patients required no further imaging, and 25% were able to avoid unnecessary laparotomy.⁷⁷ Overall, EUS changed clinical management significantly in as many as one third of the 537 patients studied.⁷⁷ Nevertheless, despite the high diagnostic yield achieved with EUS-guided biopsy, results that are negative for tumor should not always be interpreted as proving that no tumor is present; laparoscopic or open biopsy may still be indicated.

DIAGNOSTIC LAPAROSCOPY

The available evidence now clearly supports the role of laparoscopy in the diagnosis and management of abdominal masses. We and others advocate the liberal use of laparoscopy as a primary staging tool for upper and lower GI malignancies, believing it to be a safe, cost-effective tool that offers a clear benefit in more than 20% of patients with these diseases.^{78,79} Preventing unnecessary laparotomy in selected patients by performing diagnostic laparoscopy is associated with shorter hospital stays and earlier initiation of locoregional or systemic therapy. Moreover, laparoscopic ultrasonography⁸⁰ and peritoneal cytology⁸¹ are known to provide added value in the staging of disease. Furthermore, diagnostic laparoscopy can safely provide tissue samples from suspected lymphomatous masses for full diagnostic analysis.⁸² With the growth of dedicated minimally invasive fellowships and the improved quality and availability of laparoscopic training for general surgery residents and related subspecialties, the skill sets required for diagnostic laparoscopy are coming to be more widely mastered, and the concerns once commonly expressed regarding intra-abdominal adhesions and effective biopsy techniques for abdominal masses now appear to be less problematic.

Indications for Exploratory Laparotomy

Advances in diagnostic imaging, endoscopy, and minimally invasive surgery have nearly eliminated the need for open exploration for the sole purpose of establishing a diagnosis in patients with an abdominal mass. In selected cases, however, exploratory laparotomy may still help in the assessment of abdominal masses that were initially misinterpreted on preoperative evaluation. In general, exploratory laparotomy should be reserved for those rare instances in which other modalities have failed to yield crucial information needed for evaluation and diagnosis of an abdominal mass.

Approach to the Jaundiced Patient

The term “jaundice” refers to the yellowish discoloration of skin, sclerae, and mucous membranes that results from excessive deposition of bilirubin in tissues. It usually is unmistakable but, on occasion, may manifest itself subtly. Jaundice develops when serum bilirubin levels rise above 34.2 mmol/L (2 mg/dL)¹; however, the appearance of jaundice also depends on whether it is conjugated or unconjugated bilirubin that is elevated and on how long the episode of jaundice lasts.

In what follows, we outline a problem-based approach to the jaundiced patient that involves assessing the incremental information provided by successive clinical and laboratory investigations, as well as the information obtained by means of modern imaging modalities. We also propose a classification of jaundice that stresses the therapeutic options most pertinent to surgeons. We have not attempted a detailed review of bilirubin metabolism and the various pediatric disorders that cause jaundice; such issues are beyond the scope of this chapter. Finally, we emphasize that modern decision making in the approach to the jaundiced patient includes not only careful evaluation of anatomic issues but also close attention to patient morbidity and quality-of-life concerns, as well as a focus on working up the patient in a cost-effective fashion. For optimal treatment, in our view, an integrated approach that involves the surgeon, the gastroenterologist, and the radiologist is essential.

Clinical Evaluation and Investigative Studies

HISTORY AND PHYSICAL EXAMINATION

When a patient presents with a skin discoloration suggestive of jaundice, the first step is to confirm that icterus is indeed present. To this end, the mucous membranes of the mouth, the palms, the soles, and the sclerae should be examined in natural light. Because such areas are protected from the sun, photodegradation of bile is minimized; thus, the yellowish discoloration of elastic tissues may be more easily detected. Occasionally, deposition of a yellowish pigment on skin may mimic jaundice but may, in fact, be related to the consumption of large quantities of food containing lycopene or carotene or drugs such as rifampin or quinacrine. In these cases, the skin is usually the only site of coloration, and careful inspection of

sclerae and mucous membranes generally reveals no icteric pigmentation. In certain cultures, long-term application of tea bags to the eyes may lead to a brownish discoloration of the sclerae that can mimic jaundice (M. Jabbari, personal communication, 1994).

DIRECT VERSUS INDIRECT HYPERBILIRUBINEMIA

Once the presence of jaundice has been confirmed, further clinical assessment determines whether the hyperbilirubinemia is predominantly direct or indirect. This distinction is based on the division of bilirubin into conjugated and unconjugated fractions, which are also known, respectively, as direct and indirect fractions on the basis of their behavior in the van den Bergh (diazo) reaction.² If the patient has normal-colored urine and stools, unconjugated bilirubin [see *Sidebar Unconjugated (Indirect) Bilirubin*] is predominant [see *Table 1*]. If the patient has dark urine, pale stools, or any other signs or
